WASHINGTON UNIVERSITY SCHOOL OF MEDICINE

Announces the following course in

OPHTHALMOLOGY

An eight months' course in Ophthalmology for those beginning the study of diseases of the eye.

Only graduates of medical schools who have completed a year of intern service will be admitted to the course.

The course will begin October 2, 1939. Fee for the course is \$800.00.

For further information apply to
The Registrar

GILL MEMORIAL EYE, EAR AND THROAT HOSPITAL

presents its thirteenth Annual Spring Graduate Course in Ophthalmology, Otology, Rhinology, Laryngology, Facio-Maxillary Surgery, Bronchoscopy and Esophagoscopy, from April 3rd to 8th, 1939.

THE FACULTY Guest Members

Dr. Joseph E. J. King, New York, N.Y.
Dr. Hugh H. Young, Baltimore, Md.
Dr. Edward A. Looper, Baltimore, Maryland.
Dr. Warren T. Vaughan, Richmond, Va.
Dr. C. Stewart Nash, Rochester, N.Y.
Dr. James A. Babbitt, Philadelphia, Pa.
Dr. Henry M. Goodyear, Cincinnati, Ohio.
Dr. W. W. S. Butler, Roanoke, Virginia.
Dr. Harry P. Schenck, Philadelphia, Pa.
Dr. Lawrence T. Royster, University, Virginia.
Dr. Robert H. Ivy, Philadelphia, Pa.
Dr. W. Edward Chamberlain, Philadelphia, Pa.
Dr. Meyer Wiener, St. Louis, Missouri.
Dr. Alfred Bielschowsky, Hanover, N. Hampshire.
Dr. Willis S. Knighton, New York, N.Y.
Dr. Raymond E. Meek, New York, N.Y.
Dr. Edmund B. Spaeth, Philadelphia, Pa.
Dr. P. Chalmers Jameson, Brooklyn, N.Y.

Resident Members

Dr. Elbyrne G. Gill, Roanoke, Virginia.
Dr. John E. Alexander, Roanoke, Virginia.
Dr. Keith E. Gershow, Roanoke, Virginia.
Dr. Max L. Holland, Roanoke, Virginia.

GREENS' Capsule Forceps

A NEWLY modified capsule forceps for intra-capsular extraction of cataracts. It differs from the Kalt and Arruga forceps in that the lower surface of the blade is concave, thus placing it in apposition to the convex lens surface. It is shaped to meet a convexity of Plus 8-d, and the jaws are long enough to allow grasping a larger surface of capsule.

All details are executed with utmost care, with precision and fine workmanship.

Made by STORZ, in U. S. A.

SO THEY MAY KNOW...

● In the interest of more comfortable vision, a national educational program is again being undertaken by our company. This is a vigorous, ethical continuation of the program started in 1937. This effort has been reviewed and endorsed by medical authorities. It is our fixed policy to consult the members of your profession and others on the essential points of public education—and as to the manner of presenting the facts. There is no attempt to prescribe—no suggestion that Soft-Lite Lenses should be worn by everyone for whom glasses are prescribed. We simply suggest that this finest *quality* neutral absorptive lens, made at Bausch & Lomb, may be prescribed when an absorptive lens is indicated in your refraction... It is our hope that this educational program will exert a desirable influence on your present patients and create prospective ones.

THE OTTO BARKAN FOCAL ILLUMINATOR

This new lamp is only 4½ inches over all and weighs 5 ounces.

It may be held in the hand, mounted on a floor stand, or mounted directly on a Corneal Microscope Head or Micro-Gonioscope.

It furnishes a patch of light 2½ inches in diameter of 100 foot-candles at 5 inches distance; a patch of light 7/8 of an inch in diameter of 500 foot-candles at 5 inches distance; and a brilliant slit image of the filament. It therefore serves as a small "Hammer" lamp and a hand slit lamp.

Operating on 8 volts, the transformer is an integral part of the wall plug. The lamp remains remarkably cool even after long burning. The price is \$25.00 with handle, cord, and transformer.

Announcing . . .

The New National Ophthalmoscope

featuring

The All-Molded Battery Handle

Precision rotary voltage control.

No paint or plating to wear or chip—no exposed metal parts to "short." Beautiful in design.

Binding posts to accommodate *all cord-operated instruments.*

Make Comparisons and You Will be Content with No Less

"Neicomold" Ophthalmoscope incorporates *magnified illuminated numerals*. Double-Disc Ophthalmoscope provides specialists' range of 96 lens combinations plus color filters for red-free, day-light and clear light.

Slit Light Cap Set

Developed in conjunction with Long Island College of Medicine, Department of Ophthalmology.

Permits projection of a *streak of light* upon the eyeground, as advocated for the recognition of *depressions and elevations.*

Telescopic Magnifier

Developed in conjunction with Long Island College of Medicine, Department of Ophthalmology.

Doubles magnification of the area under examination, thus increasing diagnostic efficiency.

Polarizer Attachment

This inexpensive attachment instantly converts a standard ophthalmoscope, *applying the remarkable properties of polarized light* to the eyeground and ocular tissues.

IRIDOCAPSULOTOMY SCISSORS

By Conrad Berens, M.D.

For cutting dense secondary membranes and in performing iridocapsulotomy, the Berens Scissors has several advantages.

Very thin and narrow, pointed and slightly curved, the blades are 14 mm. long. Having duck bill action, the disadvantages of the usual cross-scissors type are avoided as the blades are always closed except when pres-

sure is exerted. This makes easy introduction and manipulation in the anterior chamber.

This iridocapsulotomy scissors can be used through a smaller opening than can the de Wecker type. The blades completely fill the scleral opening made by the narrow Berens Keratome, thus preventing unnecessary loss of vitreous. Chrome plated. Each,

**NEW****Improved Verhoeff's Capsule Forceps
for Intracapsular Extraction**

Frederick H. Verhoeff, M.D.

A straight capsule forceps with jaws meeting evenly everywhere. They are so adjusted that no matter how much pressure is put on the forceps, they will not close any more tightly than they are adjusted.

Part of the curve of the jaw is not that of a circle but of an ellipse. The lower blade is flush with the arm of the forceps, so that the lens can be easily grasped at the equator. "The upper blade is open for better observation and is somewhat thicker so as to be stronger, and also to open the wound a little wider."

This set-off behind the jaws leaves a space between the branches to avoid pinching the iris.

SHAHAN OPHTHALMIC SLIT LAMP

With New LUCITE Transilluminating Cones

A single, inexpensive instrument, the Shaham Slit Lamp provides an intense light beam for examinations, brilliant enough for needling; a slit for gonioscopy, invaluable for noting elevations and depressions; oblique illumination for observing blebs, opacities, polar cataracts, etc.; and, the finest ocular transilluminator available. New Lucite Tip A throws brilliant light at approximately right angles from the axis of the lamp. Tip B has a lesser curve, to transilluminate the eyeball from the back. The lamp uses an ordinary 6-volt bulb and does not get hot in use.

Shahan Slit Lamp, with 1 Lucite tip and adapter, \$25.00

Tip A, only, with adapter, \$7.50
Tip B, only, with adapter, \$7.00

BERENS' IRIDOCAPSULATOMY SCISSORS

Made by Storz, in U.S.A.

The outbreak of war has cut off European Supplies of Surgical Instruments. We are happy to announce that we are able to make many of the finer eye instruments here, in our own shop. They are made with the same precision and fine workmanship as the finest of the imported instruments.

The delicate, slightly curved blades of the improved Berens' scissors facilitate the introduction into the anterior chamber. The blades are opened by compressing arm and spring and closed by releasing. The spring is strong enough to cut dense secondary membrane.

Stereoscopic Cards in Color . . . for Children and Adults

By CONRAD BERENS, M.D., New York, N.Y.

For Use in Stereoscopes and Major and Minor Amblyoscopes

THE RESTORATION of normal binocular vision and the development of stereopsis, especially in children, may be aided by interesting stereoscopic cards. The use of well-known subjects is of importance in order to maintain interest. These colored cards stimulate the desire for fusion more than the usual black and white cards.

FACIAL HEMIATROPHY*

A REPORT OF TWO CASES

FRANK B. WALSH, M.D.

Baltimore, Maryland

Facial hemiatrophy deserves mention in current ophthalmological literature because ocular changes, although usually inconspicuous, may be observed. The purpose of this paper is to report two cases and to indicate the present state of knowledge on the subject.

There are two important types of the disease: the congenital nonprogressive, and the more frequent progressive facial hemiatrophy. Congenital facial hemiatrophy has been recorded rarely. It is characterized by congenital hypoplasia with subsequent retardation of growth (Wartenberg¹). Case 1 here reported presented a classical picture of this abnormality.

CASE 1

I. G. (104, 047), a white boy, age 13 years, was examined in the dispensary clinic of the Johns Hopkins Hospital in March, 1937. He complained of poor vision in the right eye noticed three months before his visit to the dispensary. The right side of his face has been flatter than the left since birth.

He was the fifth of seven children, all of whom were normal except the patient. His birth was normal. His mother noticed immediately that his right cheek was

yellow and covered with fine hair and appeared flatter than the left. The upper right gum became swollen and sore at seven years of age, but no teeth had appeared. The unerupted deciduous teeth were later extracted.

Examination showed a facial asymmetry, the right side of the face being much flatter than the left. On the right side there was much lanuginous hair with atrophy of the muscles and wrinkling of the skin. The right outer canthus was displaced downwards. There was no motor paralysis nor sensory change in the involved region.

Examination of the right eye showed the lids, lacrimal apparatus, conjunctiva, cornea, anterior chamber, iris, tension, and external ocular movements to be normal. The pupil was round, regular, and reacted to light and on convergence, and was of the same size as that of the left eye. There was no enophthalmos. Ophthalmoscopic examination showed a large central pigmented chorioretinal lesion which involved the macula. The remainder of the fundus was normal. The left eye was normal throughout. Vision in the right eye was 10/200, in the left 20/15.

Roentgenograms showed that permanent teeth were present in the upper right gum. None had erupted. The frontal and maxillary sinuses and the basal foramina were smaller on the right than on the left. Figure 1 illustrates the appearance

*From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University. Read before the Section on Ophthalmology, Baltimore City Medical Society, February 24, 1938.

of the patient at the time of admission.

Progressive facial hemiatrophy is not an extreme rarity. J. Purves Stewart² described the disease as follows: "This disease, which commences in early life, usually before puberty, and more often in females than in males, shows itself first in the skin of the face, either near the orbit or over the upper or lower jaw, gradu-

Progressive facial hemiatrophy has been observed as an accompaniment of scleroderma so frequently that it is considered by some authorities to be a definite form of that disease. Syringomyelia may result in either hemiatrophy or hemihypertrophy. Hemiatrophy has been reported as following epidemic encephalitis (Mankowski³). It has followed Klump-

Fig. 1 (Walsh). Congenital (nonprogressive) facial hemiatrophy. Case 1.

ally spreading over the whole face on one side. The skin becomes thinned from atrophy of the papillary layer, the subcutaneous fat disappears, and thus the affected side of the face becomes wrinkled and furrowed in marked contrast with the healthy side. Later the subjacent muscles, cartilages, and bones become atrophied, but without motor paralysis or reaction of degeneration. The corresponding side of the tongue, when protruded, comes straight out, unlike that of a patient with atrophy from hypoglossal palsy. The hair on the affected side may fall out or become white, and the sebaceous glands may atrophy. The scalp rarely is affected. There is no anesthesia." This concise description suffices for many classical cases, but others are recorded in which more complicated pictures were present.

ke's paralysis and infantile hemiplegia, but with these conditions this paper is not concerned.

Associated symptoms and signs have been: (1) contracture of muscles of the affected side of the face. Sachs's⁴ patient exhibited clonic then tonic spasms of the temporal and masseter muscles which spread to the tongue on the atrophic side. Convulsive tic was noted by Oppenheim,⁵ and intention tremor of the upper extremity on the same side by Claude.⁶ (2) Hemicrania was observed by Oppenheim. (3) Jacksonian epilepsy has been observed in many cases (Wartenberg,¹ Wolff⁷). Calcification of the brain and epilepsy were recorded by Merritt, Faber, and Bruch.⁸ These cases have some weight in pointing to a possible cerebral focus as the causative agent in the condition. (4) Recurrent herpes was

observed by Trotter.⁹ (5) Tachycardia was noted by Jendrassik.¹⁰ (6) Esophageal dilatation was recorded by Claude and Cantraine.¹¹ (7) Shumway¹² has reported the case of a patient who exhibited facial paralysis, optic neuritis, and facial hemiatrophy on a basis of polyneuritis. Facial hemiatrophy also has been observed with facial paralysis (Wartenberg¹), but Gower¹³ is authority that true facial hemiatrophy never results from facial paralysis. (8) Acromegaly was observed by Harbitz.^{13a} (9) Pigmentation of the skin has been observed frequently. (10) Ocular changes have been noted frequently and are described separately.

Obviously progressive facial hemiatrophy is a misnomer when the process involves other parts of the body. It may commence in the upper triangle of the neck (O. Fischer¹⁴). The shoulder girdle on the same side of the body as the affected face, or the whole of one side of the body may be involved in the process (Oppenheim,⁵ Finesilver and Rosow¹⁵). The face on one side may atrophy with a coincident atrophy of the trunk and limbs on the opposite side (Lunz,¹⁶ Bernstein¹⁷), or a facial hemiatrophy may occur in association with pigmentation on the opposite side of the body (Volhard¹⁸). Bilateral hemiatrophy (Schlesinger) occurs not infrequently (Archambault and Fromm²⁰).

Case 2 here reported is an example of progressive facial hemiatrophy, and is especially interesting in that the patient suffered from heart block, a complication hitherto unreported in facial hemiatrophy. Only the essential details of this case are presented.

CASE 2

L. C. (H.L.H. 72,374), a white girl, was first seen in June, 1931, at which time she was five years old. She was

brought for admission because of a difference in the two sides of her face.

Past history: She was the third child of the family, having two brothers who were two and four years older, respectively. Both siblings developed normally. The parents were healthy without developmental defect. During her fifth year she contracted measles, chickenpox, and influenza. One month before examination in this hospital she had whooping cough. One year before her examination here she had been hospitalized elsewhere, at which time a diagnosis of heart block was made. She recovered from this after a few months. The cause was not ascertained.

Present illness: At the age of three years her mother noticed a bluish tint in the skin at the left corner of her mouth. Two or three months later it was observed that the left lip had become thinner than the right and was drawn outward. About this time a hollow above the left upper eyelid appeared. The whole left side of the face gradually became smaller than the right side. There was no complaint of twitchings of the facial muscles, of pain, or of abnormal sensations in the affected area. There was no visual defect.

Examination (June, 1931), age five years: The patient was a rather frail child with no complaints, with normal temperature and fast pulse (130). General physical examination revealed no abnormality other than that of the face.

The head was of normal shape and size. The face was asymmetrical. Above the left eye the forehead contour showed a large shallow depression about 3 cm. in diameter. The outline of this depression was definite and its walls sloped gradually inward. The face showed thinning of the upper lip on the side with thinning of the buccal mucosa. There was an indistinct line of pallor and atrophy 0.5 cm. wide

extending upward, just lateral to the left side of the nose and medial to the inner canthus of the left eye and merging with the atrophic area on the forehead. The veins of the left side of the face were not dilated. Over this area the skin was thin and freely movable over the underlying structures. The color of the skin was unchanged, but tiny dimpled areas

higher on the affected side than on the normal side. Subsequently this difference was not found.

A diagnosis of facial hemiatrophy was made.

Second admission (1933), age seven years: The facial atrophy appeared more advanced. In addition, there was an abnormally slow pulse rate of 44. An ad-

Fig. 2 (Walsh). Progressive facial hemiatrophy. Patient in case 2 at five and eight years of age.

were present in it over the involved areas. Palpation gave the impression that there was thinning of the underlying structures.

The eyes appeared to be normal, with pupils, equal in size, which reacted normally to light and on convergence. External ocular movements were normal. The ophthalmoscopic examination was negative, bilaterally.

Laboratory tests, including Wassermann reaction on the blood, were negative. Roentgenograms showed clouding of the left antrum.

Special tests: On this admission it was thought that the electrical resistance and the temperature of the skin were slightly

ditional change in the face was thinning of the soft palate on the left. The left maxilla had become much wasted. The nasal bones on the left side were smaller than those on the right. The upper left gum was thickened and the teeth in that region were irregular. The mandible and the tongue were not affected. There was no alteration of sensibility nor demonstrable weakness of the muscles. The cranial nerves remained normal.

General examination showed slight cardiac enlargement. The apex beat was in the sixth interspace 4.5 cm. outside the mammary line. The blood pressure was normal. Other examinations, includ-

ing laboratory tests, gave negative results.

Examination of the eyes showed them placed at different levels, the left eye appearing higher than the right. There was no diplopia. There was definite enophthalmos (not measured) of the left eye. No difference in the width of the lid slits was observed. The extraocular movements were normal. The conjunctivae and corneae were normal. The pupils were regular, of equal size, and reacted promptly to light and on convergence. Vision of the right eye 20/30; of the left eye, 20/30. The optic fundi were normal. Corrected vision O.U. was 20/20.

Further X-ray studies showed the left frontal sinus to be larger than the right. There was no apparent change in the bones of the skull. Blood sugar and sugar tolerance curves were normal. Phthalein excretion was 78 percent in two hours; N.P.N. was 39 mgm. percent; B.M.R. was —18.

Special tests: A series of tests was performed using pilocarpine (1/20 gr. in 10 minims of water). Pilocarpine injections produced perspiration under the armpits and flushing of the face on both sides. Local injections in the regions of the orbits caused profuse lacrimation of both eyes.

A series of electrocardiogram records was obtained. These showed a third-degree heart block (complete auricular-ventricular dissociation) which was not altered by repeated injections of atropine sulphate. The oculo-cardiac reflex showed a ventricular slowing from 45 to 41.

Interval 1933 to 1937: During this period there were no important new developments other than a gradual increase in the atrophic process. Heartblock was present constantly. The patient attended school. She was admitted and examined on two occasions, but nothing materially was added to the clinical picture.

Fifth admission (1937), age 11 years:

She was readmitted in March with a history that four months prior to this admission she had had a spell of numbness of the left side of the face and right hand and inability to speak for a period of 15 minutes. This was followed by nausea without vomiting or headache. Following this attack she had frequent attacks of nausea with a sensation of numbness in the tongue and left hand. These later spells were followed by severe headache in the left temporal region. On one occasion while in the hospital she complained of a headache followed by a sensation of haziness of vision and numbness of the right hand and lower arm. Examination of the eyes showed no change from the examination made in 1933. She contracted diphtheria, and was discharged to another hospital.

Summary of history: A girl three years old developed leftsided facial atrophy which progressed during the six years she was under observation. When she was four years old heart block appeared, and was recovered from, but recurred three years later and persisted during the remainder of the period of observation. Eight years after the onset of the facial hemiatrophy spells of numbness in the face and superior extremities occurred. Extensive studies failed to establish cause for the heart block. Special tests designed to establish involvement of the sympathetic nervous system were negative.

COMMENT

Since Jarry (Chasanow)²¹ in 1837 and Romberg²² in 1846 described progressive facial hemiatrophy, the cause of the disease has remained obscure. A review of the theories of etiology summarizes the present knowledge on the subject.

The trigeminal peripheral-neuritis theory. Mendel²³ in 1889 examined a single case at autopsy, and found a peripheral

interstitial neuritis of the fifth nerve. He cautiously suggested that this might be the basic factor in initiating the disease process. Mendel's findings were later duplicated in another autopsy case (Loebel and Wiesel).²⁴ However, in 1914 Grabs²⁵ found no involvement of the trigeminal nerve or any part of the central nervous system.

Pain in the region of the fifth-nerve distribution is a frequent symptom and may be a precursor of hemiatrophy (Oppenheim).⁵ However, typical trigeminal neuralgia is not followed by hemiatrophy. The trigeminal neuritis theory seems to be invalid because (1) section of the sensory root of the trigeminus does not result in facial hemiatrophy; (2) the atrophic process does not start invariably in, or remain in, the region of trigeminal innervation.

Although the trigeminal-neuritis theory as such appears invalid for the reasons stated above, it has been suggested that frequent limitation of the process to the region of the fifth-nerve innervation is due to involvement of the sympathetic fibers which accompany the fifth nerve. Thus it is thought to be a "trophoneurosis."

The sympathetic theory. Involvement of the cervical sympathetic probably through vasomotor control has been considered frequently as the cause of the condition (Sachs,⁴ Cassirer,²⁶ Siebert²⁷). Trauma has been recorded as an initiating factor (Bost²⁸).

In the earlier work, involvement of the peripheral sympathetic system was considered principally. Oppenheim, in his excellent review, includes cases following tuberculous infections of the apex of the lung, extirpation of the glands of the neck, and direct injuries to the face and neck, all of which might affect the cervical sympathetic system. Manthey²⁹ described facial hemiatrophy following thy-

roidectomy and remarked that signs of sympathetic injury occurred only 12 times in 1,196 thyroid operations (Kaelin's series).

On the basis of the "trophic" nature of the lesions, many authors thought there was involvement essentially affecting the sympathetic system, either through the cervical sympathetics or central sympathetic tracts, including the parasympathetics. Stief³⁰ reported the autopsy findings in a case of right-sided, progressive hemiatrophy with scleroderma in a woman of 64 years (the oldest case observed) over a period of four years. There was generalized sclerosis of the central vessels, and the brain itself showed various stages of necrosis with an interesting difference in the two hemispheres. The left hemisphere in its entirety showed coagulative necrosis, apparently from anemia; whereas the right hemisphere showed vascular dilatation and stasis. This difference between the right and left halves was less marked in the brain stem than in the hemispheres. Stief also found round-cell infiltration in the right cervical ganglia. He thought that the vasomotor change in both hemispheres was dependent upon involvement of the cervical sympathetics—that on the right to vasomotor paralysis and that on the left to vasomotor irritation. He thought that the hemiatrophy in his case was due to destruction of the opposite thalamus.

As further case records accumulated, symptoms other than facial atrophy were noted, and it became apparent that involvement neither of the trigeminus nor of the sympathetic could adequately explain the entire picture.

Epileptic fits were noted by Wolff,⁷ Wartenberg,¹ Archambault and Fromm,²⁰ Lauber,³¹ and Merritt, Faber, and Bruch.⁸ They usually commenced several years after the onset of the hemiatrophy. Case

2 here recorded is of interest in this regard.

The occurrence of fits, the occasional extensive spread of the process (Wolff,⁷ Archambault and Fromm²⁰), coincident cerebral calcification (Merritt, Faber, and Bruch⁸), ocular signs such as pupillary dilatation with loss of reflex to light (Oppenheim,⁵ Claude and Cantraine¹¹), monocular nystagmus (Langelaam³²), and ocular muscle palsies (Heiligenthal,²⁰ Sterling^{31a}) suggested central lesions. Crossed lesions in which the face on one side and the limbs and trunk on the opposite side were affected suggested midbrain lesions.

Involvement of the pyramidal tracts as reported by Claude appeared to indicate central involvement.

The infection theory. Many cases have been described as occurring after infectious diseases, and Möbius (Oppenheim⁵) thought that progressive hemiatrophy was due to some infectious process. Infection from the tonsils or following adenoidectomy has been mentioned.

Heredity of facial hemiatrophy. Klingmann³³ in this country described a family in which the grandmother, mother, and her twin daughters showed the defect. degeneration, and remarked that, in common with other such diseases, it often makes its appearance at the time of puberty. He further stated that, as in the other degenerative diseases, it may be accompanied by imbecility, congenital paralysis of the eye muscles, facial paralysis, and other conditions. However, heredity is not stressed by most authors.

Relationship between progressive facial hemiatrophy and scleroderma. It generally is agreed that differentiation between these two diseases may be difficult, if not impossible, particularly at the onset. Scleroderma does not usually occur unilaterally, but it may do so, particularly in

the circumscribed form (morphea). Some authorities (Cassirer,²⁸ Knapp³⁴) consider scleroderma and hemiatrophy to be manifestations of the same disease process. The small circumscribed patch in the skin which denotes the commencement of scleroderma usually is raised and often is of a slightly bluish or brown color, but may be depressed and free of pigment. Oppenheim, in speaking of facial hemiatrophy, stated that there might be an infiltration of the skin before the atrophy appeared, and Wartenberg described a case in which there was scarcely any involvement of the skin. Pigmentation has been observed in both diseases. For a careful differentiation the reader is referred to Osborne's³⁵ article.

The groove lying lateral to the midline in characteristic progressive facial hemiatrophy may contain hard immobile skin as in scleroderma. Pick³⁶ described such a case, diagnosed originally as scleroderma because of the characteristic appearance of the skin, which developed into a progressive facial hemiatrophy.

In other cases, however, the hard, shiny, thickened, immovable skin of the scleroderma patient scarcely can be confused with the smooth, thin, freely movable skin of the progressive-facial-hemiatrophy patient. The cause of scleroderma is as obscure as that of progressive facial hemiatrophy, and the same theories in regard to etiology have been put forward for each disease.

Ocular signs of hemiatrophy. Enophthalmos, sometimes of a high degree, is occasionally a striking result of progressive hemiatrophy whether or not it is associated with scleroderma. It was present in case 2 here reported. However, it has not been noted in the majority of cases. Exophthalmos has been observed.

Apparent upward displacement of the eye on the affected side was observed by Archambault and Fromm and was pres-

ent in case 2 here reported, but in neither instance was there an abnormal muscle balance.

Narrowing of the lid slit on the affected side has been observed frequently, but was not present in the case here reported. Chasanow²¹ reported a case which presented Stellwag's sign (infrequent blinking).

The extraocular muscles rarely are affected. Salomon³⁷ described the case of a girl of nine years who possibly had congenital syphilis, and in whom there was a weakness of the facial muscles and atrophy on the left side of the face. There was also paralysis of the right abducens, and partial paralysis of the third nerves innervating the internal recti. The vision was relatively good. There were no pupillary reactions to light nor to convergence on either side. Lacrimation was normal. Sterling^{31a} also reported abducens paralysis. Finesilver and Rosow¹⁵ recently reported a case of complete unilateral hemiatrophy with enophthalmos, slight lagophthalmos, atrophy of the nasal half of the upper margin of the lid, contraction of the conjunctival sac, and impairment of all extraocular movements. Monocular nystagmus was reported by Langelaam.³² Heterochromia iridis has been reported (Lauber,³¹ Pick³⁶).

Pupillary signs have been recorded, but are not uniform. The pupil may be dilated and fixed to light on the same side as the atrophy (Stief,³⁰ Archambault and Fromm,²⁰ Oppenheim⁵) or on the opposite side (Langelaam³²). In several instances where the pupil was narrowed, paralysis of the sympathetic fibers was evidenced by failure of the pupil to dilate with cocaine or adrenalin (Stief,³⁰ Stiefler³⁵). But in many instances the pupillary reactions were normal. Accommodation may be affected (Archambault and Fromm²⁰).

Vision was not affected in the great

majority of the reported cases. Optic atrophy was noted in a few cases (Heiligenthal and Abadie quoted by Surat,²⁹ Claude and Cantraine¹¹).

SUMMARY OF OCULAR SIGNS

Ocular signs are not constantly observed in facial hemiatrophy. When present, the principal ones are enophthalmos, rarely exophthalmos, narrowing of the lid slit, and pupillary changes. It is noteworthy that Horner's syndrome in its entirety is rather a rarity, and miosis, which is the most definite indication of an injury to the sympathetic chain, seems to occur no more frequently than does dilatation of the pupil. The latter may be ascribed in these cases to injury to the parasympathetics. However, the dilated pupils may be examples of "tonic" pupils and, therefore, have no known significance. Salomon's case loses some of its value because of the possible presence of congenital syphilis, but would indicate an extensive central lesion. Monocular nystagmus has been reported only once, and was not clear cut in that case. Heterochromia iridis has been observed rarely. It would seem to indicate sympathetic involvement during an early period of life.

The function of the eye usually is not affected.

Cardiac action in progressive facial hemiatrophy. Several authors, among them Jendrassik,¹⁰ noted a persistent increase in the pulse rate. Case 2 here reported is, so far as I am aware, the only case report of facial hemiatrophy associated with heart block. This association is probably coincidental.

The special tests in progressive facial hemiatrophy. Tests designed to reveal hyper- or hypoactivity of the sympathetic nerves have been performed in many cases, but the results were not uniform.

The most important tests are: (1) co-

caine instillations, which fail to dilate the pupil when sympathetic innervation is interrupted, or (Stiefler³⁸) accelerate dilatation when the sympathetics are stimulated; (2) pilocarpine injections, which fail to produce sweating on the area in which there is loss of sympathetic innervation; (3) temperature estimations when there is elevation of temperature in the area of sympathetic loss. In case 2 here recorded the two last-mentioned tests were negative.

Interesting conditions described in the literature may be associated with or related to facial hemiatrophy. These are: (1) hemihypertrophy, which occurs less frequently than hemiatrophy but has been reported as occurring in association with it (Sterling²⁰). (2) Lipodystrophy as described by Ziegler.⁴⁰ (3) A symptom

complex described by Passow⁴¹ under the title "Horner's syndrome, heterochromia, and status dysraphicus." Passow's paper has recently been reviewed adequately by Pino, Cooper, and Van Wien.⁴² (4) A syndrome is described by Fuller, Albright, *et al*.⁴³ under the title "Syndrome characterized by osteitis fibrosa disseminata, areas of pigmentation, and endocrine dysfunction with precocious puberty in females."

CONCLUSION

Two cases of facial hemiatrophy have been described. One was congenital, and for this reason merits recording because of its rarity. The other case deserves recording because the combination of progressive facial hemiatrophy and heart block has not been reported previously.

STAPHYLOCOCCUS TOXIN*

AN EXPERIMENTAL STUDY IN RABBITS

J. H. ALLEN, M.D. AND A. E. BRALEY, M.D.

Iowa City

Toxins prepared from staphylococci isolated from general sources have been shown to exhibit several activities,¹⁻⁵ lethal, hemolytic, leucocytolytic, dermo-necrotic, enterotoxic and perhaps others. Several of these properties have been shown for filtrates prepared from staphylococci isolated from ocular sources.^{6, 7} This study was instituted in a further effort to correlate the properties of ocular types of staphylotoxin with those of general types. However, early in the problem normal rabbits were found to vary in susceptibility to the toxin. This phenomenon⁸ has been observed by other workers. Ramon, Richou, and Descazeaux⁹ have shown that a considerable proportion of normal rabbits possess "natural" antitoxin in their serum. This has been confirmed by Roy.¹⁰ However, Glynn¹¹ has suggested that variation in potency of the toxin also may account for the so-called variation in susceptibility of normal rabbits. Therefore, in this study the antitoxin titer of the serum of the rabbits was determined, and the potency of the toxins was titrated against standard toxin and antitoxin furnished by the National Institute of Health.

METHODS AND MATERIALS

The 10 strains of staphylococci employed in making the toxins were isolated from cases of conjunctival inflammation. These organisms produced a yellow pig-

ment on plain and blood agar, a yellow or purple growth upon crystal violet agar,¹² and produced acid in mannite media. Each strain caused coagulation of citrated human serum¹³ and produced hemolysis upon both sheep's-blood agar and rabbit's-blood agar.

Toxin was prepared from each strain of organisms by a modification of the method of Leonard and Holm¹⁴ as previously described by the senior author.⁶ Just prior to administration of the toxin, it was titrated by the hemolytic method against standard toxin and antitoxin.

The provisional standard unit of toxin, an Lh dose, has been defined as that amount of toxin which, when mixed with one standard unit of antitoxin, will cause approximately 20-percent hemolysis of 1.0 c.c. of a 2-percent solution of packed red blood cells (rabbit). The toxins prepared for these experiments were standardized in Lh units and found to range between 8 and 10 per cubic centimeter. The Lh unit, however, was too large for estimations of the "natural" antihemolytic titer of rabbit serum; therefore, a subdivision was sought. A minimal hemolytic dose (MHD) was adopted—one which would just produce complete hemolysis of 1 c.c. of a 1-percent solution of packed red blood cells. Under the test conditions one Lh unit of the standard toxin was found to contain 200 MHD.

One hundred normal rabbits weighing from 0.8 to 3 kilograms were inoculated with amounts of toxin varying from 160 to 1,500 MHD (200 to 500 MHD per kilogram). The serum of each of 70 rabbits was titrated for its antihemolytic activity. Varying dilutions of serum were

*From the Department of Ophthalmology, State University of Iowa, College of Medicine. Part of a study being conducted under a grant from the John and Mary R. Markle Foundation. Read before the Association for Research in Ophthalmology in San Francisco, June 14, 1938.

added to tubes containing 2 MHD (1/100 Lh dose) of toxin; the volume in each tube was made up to 2 c.c. with normal saline, and the mixtures were incubated in a constant-temperature water bath at 37°C. for one hour. One cubic centimeter of a 1-percent solution of packed rabbit red blood cells, which had been washed in saline three times, was added to each tube. The tubes were left in the water bath for one hour, then placed in a cold room over night. Control tubes containing standard toxin and antitoxin were set up with each titration. In this manner it was possible to estimate antihemolytic activity to 1/200 unit. However, titrations to this fraction are not accurate because of the principle of neutralization in multiple proportions, and some workers¹⁵ believe that below the level of 1/10 unit per cubic centimeter of serum the reaction is not specific.

In the beginning of the study the rabbits were given 200 to 500 MHD per kilogram in the marginal ear vein; as some of these survived, serologic studies were instituted. For this purpose approximately 10 c.c. of blood were drawn from one of the large superficial neck veins and 24 to 48 hours later toxin was administered intravenously.

A complete post-mortem examination was made immediately after death of the rabbit. Tissues were fixed in Zenker's fluid, sectioned in paraffin and stained by hematoxylin and eosin.

SEROLOGIC FINDINGS

The serum of 16 of the 70 rabbits was found to contain antihemolysin; however, only 9 contained an amount sufficient to protect against the toxin administered. Five rabbits possessing 0.5 units of antitoxin per cubic centimeter were protected against doses of 500 MHD per kilogram. The rabbits possessing less than 0.1 unit per cubic centimeter apparently were not protected against the toxin inoculations, thus perhaps lending support to the view

that with such small amounts the reaction is not specific.

PATHOLOGIC FINDINGS

The survival time varied inversely with the size of the dose of toxin per kilogram of body weight. The rabbits receiving the larger doses died in 3 to 5 minutes and those receiving the smaller doses died in 30 to 60 hours.

Rabbits dying in 3 to 5 minutes usually had one short violent convulsion ending in

TABLE 1
ANTITOXIN TITRATIONS

No. of Rabbits	Anti-hemolysin per c.c. of Serum	Dose of Toxin per Kg.	Fate
41	Not titrated	200-500 MHD	Died
5	Not titrated	200-500 MHD	Survived
5	0.5 unit	500 MHD	Survived
2	0.2 unit	500 MHD	Survived
2	0.1 unit	200 MHD	Survived
2	0.02 unit	200 MHD	Died
5	0.01 unit	200 MHD	Died
54	0.00	200-500 MHD	Died

a high-pitched squeal. Those surviving for a longer period exhibited symptoms of restlessness, increased rate of respiration, weakness, and passage of urine and feces. After lying quietly on the floor for a time, convulsive running movements developed and after one or more high-pitched squeals, the animals died.

In order to minimize the possibility of post-mortem tissue changes, autopsies were done immediately after the squeal. Heart action had ceased except for some fibrillation of the auricles; however, peristaltic movements usually continued for several minutes.

GROSS PATHOLOGY

Rabbits dying within 30 minutes after administration of the toxin exhibited very little gross pathology, but as the survival time increased the amount of congestion, hemorrhage, and necrosis increased. There was a variable amount of serous fluid in the pericardial sac. Usually the

left ventricle was in systole and the right in diastole. There were occasional sub-pericardial petechial hemorrhages in the animals surviving for longer periods. Petechial hemorrhages and small hemorrhagic areas were present in the lungs, the number and extent being in direct proportion to the time of survival. In the smaller rabbits there were superficial hemorrhages in the thymus. The liver was purplish brown, distended by an active congestion, and an occasional small sub-capsular hemorrhage was seen. The spleen also was distended and purplish brown. The kidneys were most constantly affected, but here again the acute deaths were characterized by the least gross pathology. The kidneys of rabbits dying in less than 30 minutes were acutely congested and in animals surviving longer hemorrhages were present beneath the capsule. As the survival period increased the kidneys became mottled in appearance, due to yellowish-white areas of necrosis surrounded by purplish areas of hemorrhage. The capsule could readily be stripped from these areas. The adrenals were slightly congested in the acute deaths, but were mottled by hemorrhage and necrosis in the prolonged deaths. The bladder invariably was distended. There was no evidence of gross pathology in the gastrointestinal tract in any of the animals.

Ophthalmoscopic examinations were made shortly after death in approximately half of the rabbits, but no gross pathology was observed.

MICROSCOPIC PATHOLOGY

Heart: There were a few petechial hemorrhages in the epicardium, myocardium and endocardium of rabbits surviving for longer periods. In addition there was an occasional small zone of necrosis of the muscle fibers.

Lungs: In the acute deaths there were dilatation and congestion of the capillaries

with an occasional interstitial and sub-pleural petechial hemorrhage. With an increase in the survival time, the microscopic pathology increased; there were red blood cells in the alveoli in increasing numbers, and in the more prolonged deaths there were some patchy areas of necrosis of the alveolar epithelium.

Thymus: An occasional small subcapsular hemorrhage was observed in the thymus of the smaller rabbits surviving for several hours.

Liver: In the animals dying in less than 30 minutes, the liver showed dilatation of the sinusoids and central vein of the lobule, with some cloudy swelling of the liver cells. However, as the survival time increased, patchy areas of necrosis developed about the central vein of the lobule. In rabbits surviving from 30 to 60 hours the necrosis had extended outward to include all of the cells of the lobule and practically all of the lobules were affected. In a few of the rabbits there was some evidence of regeneration around the portal spaces, with the cells appearing to arise from the bile ducts.

Spleen: The spleen, like the liver, exhibited only congestion and dilatation in the more acute deaths. The sinuses were filled with red and white blood cells as well as with large numbers of mononuclear cells. There was an increase in the number of brownish pigment granules in the phagocytic cells and in the amount of free pigment in the sinuses, indicating increased hemolysis. In the animals surviving for longer periods there was some necrosis of the cells lining the sinuses and some disintegration of the pulp.

Kidney: The microscopic changes in the kidneys were the most constant. The changes after rapid death consisted chiefly of congestion and dilation of the arterioles and glomerular capillaries. However, these were of a patchy nature, for some portions of a section showed normal arterioles and glomeruli. As the survival

time increased, interstitial and subcapsular hemorrhages appeared, and there apparently were some hemorrhages into Bowman's capsule.

In those animals surviving the inoculation for 4 to 6 hours some swelling and degeneration of the epithelium of the convoluted tubules was observed. Those surviving longer showed more extensive hemorrhages, precipitates in the tubules, and in some regions dilatation of Bowman's spaces with albuminous precipitates. At this stage some of the nuclei of the tubular epithelium were pale staining, others were pyknotic. Later (24- to 60-hour survival) the nuclei had disappeared in large portions of a section, this area being surrounded by a bluish-staining zone apparently made up largely of nuclear debris, and immediately around this was a zone of hemorrhage.

Adrenal: There was a similar time relationship in the pathology of the adrenals. First there was congestion, then followed hemorrhages and necrosis. The necrosis usually involved the medulla then the cortex. The rabbits surviving 30 to 60 hours showed almost complete necrosis of the adrenals.

No microscopic changes were observed in the gastrointestinal tract or bladder.

Microscopic examination of the eyes revealed one fairly extensive choroidal hemorrhage, but no other pathology.

DISCUSSION

The pathology produced in rabbits by these ocular strains of staphylotoxin was essentially the same as has been described¹⁶ for staphylotoxin from other sources. The only difference was the failure of these strains to produce changes in the gastrointestinal tract as described by Rigdon.¹⁷

The amount of pathology in the individual animal varied inversely with the size of the dose of toxin and directly with

the survival time. Rabbits dying rapidly showed very little pathology, those surviving for a few hours exhibited patchy zones of pathology, and those surviving for several hours presented more generalized changes. This phenomenon was expected, the typical action of a potent toxic material.

The potency of the toxin was estimated in hemolytic units shortly before its use, thus controlling any variation in the toxin. Therefore as the individual dose was measured in hemolytic units, and as the pathology and the survival time were proportional to the size of the dose, it may be concluded that the hemolytic unit was a satisfactory standard for the ocular strains of staphylotoxin.

As a further control upon the pathogenic action of the toxin, the antihemolysin content of the serum of 70 of the rabbits was estimated. Nine rabbits possessing 0.1 to 0.5 units of antitoxin per cubic centimeter of serum were protected against the usual doses of toxin. This confirmed the observations of Ramon⁹ that a considerable proportion of normal rabbits possess "natural" antitoxin. It also explained the failure of comparable doses of potent toxin to kill all the rabbits in the preliminary experiments. Therefore it was concluded that all staphylotoxin studies on rabbits should be controlled by serologic studies.

CONCLUSIONS

1. The pathogenic action of ocular strains of staphylotoxin is similar to that of general strains, with perhaps the exception of the action upon the gastrointestinal tract.

2. The hemolytic unit apparently is satisfactory for estimating the potency of ocular staphylotoxin.

3. Serologic studies should be made upon all rabbits used for experimental study with staphylococci and their toxins.

DISCUSSION

DR. EDWARD JACKSON (Denver): In listening to the paper, this question occurred to me: Was any examination made of the central nervous system, or was there any manifest reason for the rapid death of the rabbits that succumbed before the viscera had given evidence of disease processes from the toxin?

DR. ALLEN: The examinations of the central nervous system were not mentioned, because microscopic examinations have not been completed. Gross pathology in the central nervous system was not different from that of the other organs.

The rabbits dying acutely exhibited very little pathology. Those which lived from 6 to 30 hours showed acute necrosis and a few petechial hemorrhages over the surface of the brain. In one rabbit a rather extensive subdural hemorrhage was noted. The few microscopic examinations that have been completed add nothing further. However, we believe the congestion, hemorrhages, and acute necrosis are similar to those found in the remainder of the organs and are sufficient to account for death.

THE INFLUENCE OF THE CENTRAL NERVOUS SYSTEM ON THE PIGMENT MIGRATION IN THE RETINA OF THE FROG*

HERMANN M. BURIAN, M.D.

Hanover, New Hampshire

In the series of objective changes which occur in the frog's retina under the influence of light, one of the most obvious is the migration of the pigment of the retinal epithelium. If a frog has been kept in complete darkness long enough, so that full dark adaptation has been achieved, the black-brown grains of the pigment are found in the bodies of the cells, outside of the layer of the rods and cones. In the retinas of light-adapted frogs, however, the bulk of the pigment is scattered within preëxistent cellular processes (Angelucci¹), between the rods and cones, reaching inward as far as the external limiting membrane. This migratory phenomenon is most evident in amphibia and fishes; it is less distinct in birds, and still less in reptiles. In mammals it can hardly be demonstrated.

Since its discovery by Boll² and Kühne³ in 1877, the reaction has been the subject of numerous studies. Outstanding among the older ones are the investigations by Engelmann⁴ and his pupil Van Genderen Stort⁵ who discovered another important functional change in the frog's retina, due also to the influence of light, the contraction of the cones.

Engelmann has been especially concerned with the influence of the central nervous system upon the migration of the pigment and the contraction of the cones and has reached the conclusion that such an influence must exist. The evidence he had was manifold. He found that in frogs and doves the reaction took place even

when only one eye was exposed to light, while the other was tightly covered and shielded from any illumination. This, however, happened only if the brain of the experimental animal was intact. After decerebration there was no reaction in the fellow eye. From this Engelmann inferred that there is an association between the cones and the pigment cells of the two eyes. Such a connection could be established only by the optic nerve, which, therefore, according to Engelmann, must contain centrifugal, retinomotor fibers. Another reflex migration of the retinal pigment can be observed in the frog when only the skin of the body is exposed to light, while a light-tight cap covers the head of the animal. Here again the pigment always assumes light position; the contraction of the cones is less evident. Finally, Engelmann could state that dark-adapted frogs, in which a strychnine tetanus was produced, showed totally expanded retinal pigment. Curare did not influence the position of the pigment. Stimulation of the eyes of dark-adapted frogs *in vivo* and *in vitro* with alternating induction currents of medium density produced the same effect.

Angelucci^{1, 6} also reported a series of observations which were in favor of a reflex migration of the pigment in the frog's retina. He found that this migration could be produced in both eyes by pressure on one eye or by mechanical irritation of the skin of the animal. He even contended that sound waves were able to produce the same effect. Herzog⁷ had similar results with mechanical stimulation and paid special attention to the influence of the temperature on the phe-

* From The Dartmouth Eye Institute, Dartmouth Medical School. Read before the Association for Research in Ophthalmology, at San Francisco, June 14, 1938.

nomenon. This had already been studied by Gradenigo⁸ and was later carefully investigated by Arey⁹ and Detwiler and Lewis.¹⁰ It has been shown conclusively that frogs, kept at certain temperatures, for a sufficient time, in complete darkness, show marked light position of their retinal pigment. The same result in fishes has been reported by Wunder.¹¹

One fact mentioned in Herzog's paper cited above is of special interest. Herzog stated that the retinal cones were unusually long in decerebrated frogs and in frogs in which the spinal cord was destroyed. This he ascribed to the lack of central tonus. Dittler¹² could not confirm this finding, but Garten¹³ found that it was true for animals in which he had severed the optic nerve. Hamburger¹⁴ saw this phenomenon in opticotomized frogs only occasionally.

Although all these results seem rather convincing, serious objections have been voiced against their conclusiveness. Fick¹⁵ in 1889 already pointed out that in Engelmann's experiments in which only one eye was exposed to light vestiges of light might have reached the other eye. In the experiments in which the head of the animal was covered with a light-tight cap and the skin of the body exposed to light, the respiration might have been impeded, creating a change in the constitution of the blood. This might act as a humoral stimulus on the retinal epithelial cells. Finally, it is possible that in the various parts of the retina there are differences as to the migration of the pigment.

Much more serious obstacles for the assumption of a nervous regulation of the pigment migration in the frog's retina arose, however, when Dittler¹² could show on isolated retinas that a full contraction of retinal cones takes place under the influence of acids. His experiments on the isolated retina of the frog kept in Ringer's solution showed that the exposure to light

causes the formation of acid products and that these products are able to provoke a maximal reaction of the cones. Similar results had been reported by Lodato,¹⁶ before those of Dittler were published. He had found by other methods that there is a close relation between the chemical reaction of the retina and the changes that occur in the layer of the rods and cones. The expansion of the cones corresponds to an acid reaction of the retina, their contraction to an alkaline reaction. Retinas of light-adapted frogs, therefore, always have a marked acid reaction, retinas of dark-adapted frogs show an alkaline reaction, rarely a neutral, and very rarely a slight acid reaction. The injection of strychnine produces an acid reaction of the retina. The same is true for faradization of the animal and, though to a lesser degree, for an elevated temperature (35°-40°C.), acting on the animal for from three-quarters of an hour to one hour.

In the light of these results it seemed quite justifiable to question, whether all the aforementioned reflex movements of the retinal pigment are really to be considered as such, and, up to this time, the current opinion expressed in all textbooks (see, for example, Kolmer and Lauber¹⁷) that treat of this question is that so far nothing has been found which would be definitely in favor of an influence of the central nervous system on the pigment epithelium of the retina.

EXPERIMENTAL INVESTIGATIONS AND RESULTS

From this short review of the literature it appears that the question as to whether and to what extent there is a regulatory influence of the central nervous system on the pigment migration in the frog's retina, is quite unsettled. The contribution to this particular problem was motivated by the results of previous experi-

Fig. 1 (Burian). Retina of normal dark-adapted frog (control animal no. 12). The bulk of the pigment is located in the body of the pigment cells. $\times 400$.

ments,¹⁸ concerning the influence of naphthalene on the spinal cord of the frog.

The experiments to which we refer showed that an appropriate dose of naphthalene administered to a frog, is able to produce a typical poisoning of the

frog. At the height of the poisoning, the frog shows absolute muscular atony and a complete lack of mechanical reflex response, while the chemical; thermal, and electrical reflex excitability remain perfectly normal. Exhaustive quantitative studies of this quite unusual reflex phe-

nomenon and the combination of naphthalene poisoning with strychnine or phenol poisoning gave results which can be summed up briefly as follows:

Naphthalene affects the center, not the periphery of the neuro-muscular ap-

paratus. The action of the poison is directed against the sensory, not the motor part of the spinal cord, and the seat of the poisoning is to be sought in the so-called intercalary neurones. Strychnine acts as a perfect antagonist to naphtha-

lene. While strychnine raises to the highest level the readiness of the central nervous system to react to mechanical stimuli, producing the well-known strychnine tetanus, naphthalene completely abolishes it. Consequently, the central tonus of the muscles is maximal in strychnine poisoning and virtually equal to zero in naphthalene poisoning. I shall not enter into the discussion of the mechanism of the strychnine and naphthalene poisoning, the study of which throws an interesting light on the functional structure of the spinal cord, but would state that the antagonism of strychnine and naphthalene extends also to the chromatophores of the skin. While a frog poisoned with strychnine is extremely light in color, due to the maximal contraction of the chromatophores, a frog intoxicated with naphthalene is almost invariably very dark, due to the full expansion of the chromatophores. This reaction of the chromatophores is another sign of the extremely high or extremely reduced central tonus in strychnine and naphthalene poisoning.

The behavior of the chromatophores induced me to investigate whether or not the two drugs had a similar antagonistic influence on the position of the retinal pigment. As mentioned before, Engelmann had already found that dark-adapted frogs poisoned with strychnine showed light position of the pigment and contraction of the cones. Hess¹⁹ on the other hand, reports in one of his papers that he repeatedly observed, at various places in the pigment epithelium of rabbits intoxicated with naphthalene, large groups of cells arranged in the form of a circle around a center in which all the pigment was located at one border of the individual cells, either at the border turned toward the center of the circle or at the border turned away from that center.

I conducted four series of experiments, each consisting of a number of individual tests. In the first series I repeated Engelmann's experiment with strychnine and invariably found that thoroughly dark-adapted frogs showed maximal expansion of the pigment—that is, marked light position—when poisoned with strychnine. Figure 1 shows the histologic section of the retina of a dark-adapted control animal, and figure 2 the section of a dark-adapted animal poisoned with strychnine.

In a second series, light-adapted frogs were poisoned with naphthalene. The retinas of these animals always showed a marked dark position of the pigment; that is, the pigment of the cells was accumulated in the body of the cell while the cellular processes were entirely free of pigment. This, together with the appearance of the retina of a light-adapted control animal, is shown in figures 3 and 4.

These two series of experiments seemed rather convincing, indicating that the position of the pigment could be controlled by influencing the central nervous system.

In order to confirm this assumption and to form an idea of the pathway by which this influence is exerted, performed two further series of experiments. In both series the optic nerve of one side—always the left one—was severed. In frogs this is done very easily through the roof of the mouth. The animals were then submitted to dark or light adaptation and poisoned either with strychnine or naphthalene. The result was unequivocal. The retina of the normal eye always showed the position which it had assumed under the influence of the poison in the animals not operated upon; however, the fellow-eye, which had been operated upon, presented a more or less intermediate position. In light-adapted frogs there was some indication of expansion of the pigment; in dark-adapted frogs the pigment was accu-

Fig. 5 (Burian). Normal frog, light adapted. Retina of the eye, the optic nerve of which was severed seven days previous to experiment (control animal no. 14). Most of the pigment in the cell bodies, some pigment scattered along the rods and cones. $\times 400$.

mulated more in the body of the cells. Figures 5, 6, and 7 clearly show this behavior.

As to the *technique* of the experiments, the following may be said:

All animals were kept under exactly the same conditions. The dark adaptation was accomplished by keeping the animals

in a completely darkened room for from 12 to 24 hours. As a further precautionary measure, the jars containing both the experimental and the control animal were covered with a thick black cloth. The strychnine poisoning was done by injecting a measured amount of 0.1 percent

solution of strychnine nitrate into the dorsal lymph sac of the animal. The injection was performed in complete darkness; the enucleation at the height of the strychnine tetanus, with the aid of a neon light to which the control animal was equally exposed. The light-adapted frogs were kept for from 6 to 10 hours in a very light room; the administration of naphthalene was made orally, with the aid of a syringe on which a small rubber tube was mounted. The naphthalene used was an oily solution in the proportion of one

with the retina, made the further treatment of the specimens easier than if only the retinas had been used. The specimens were embedded in paraffin; their orientation in the block was such that the direction of movement of the microtome blade was parallel to the rods and cones. In this way they were not pushed together nor crushed. The sections were stained with hematoxylin and eosine.

CONCLUSIONS

It seems to me that the results of the

Fig. 7 (Burian). Light-adapted frog, poisoned with naphthalene (animal no. 20). Retina of eye in which the optic nerve had been severed 18 days previous to experiment. Essentially same distribution of pigment as in figures 5 and 6. $\times 400$.

part naphthalene to eight parts of paraffin oil. Various fixatives were tried out; the best results were obtained with Held's solution modified by Kolmer,²⁰ and we followed the technique suggested by Detwiler,²¹ fixing the bulbi for 12 hours and afterwards placing them in running water for 12 hours. The eyes were then opened at the equator and small circular pieces punched out of the posterior part of the bulbus with a trephine, which always allowed the use of analogous parts of the retinas of the various animals. The choroid and sclera, remaining in contact

experiments permit only one explanation. It has been shown clearly by pharmacological experiments that the effect of both strychnine and naphthalene is a central one; that is, that the manifestations of poisoning which were observed were due to an affection of the central nervous system. Since I was able to influence the position of the retinal pigment by the administration of these drugs, it may be assumed that this position was influenced by way of the central nervous system. In other words, the position of the retinal pigment is influenced by a central nerv-

ous tonus, as had been previously assumed by Herzog, and in the present experiments it was possible to change the position of the retinal pigment by raising or lowering this tonus. If the central tonus is brought to a maximum artificially, as is the case in strychnine poisoning, the pigment assumes a light position and is expanded even beyond the normal limit. In keeping with the accepted explanation of the effect of strychnine, it may be assumed that the excitability of the sensory part of the central nervous system has become maximal and that, therefore, stimuli of relatively low intensity lead to a maximal effect. A reflex migration of the retinal pigment, such as Angelucci found in his experiments with mechanical stimulation of the skin, would, under these conditions, be extremely favored.

The opposite is true for naphthalene. These experiments have shown that naphthalene lowers the central tonus of the muscles to a minimum, due to the reduction in the influx of impulses into the central nervous system. The sensorial part is, so to speak, blocked. According to the lack, or extremely low level, of the central tonus, light-adapted naphthalene frogs show unexpanded pigment.

The experiments of Lodato and Dittler, cited in the introduction, do not seem to invalidate my statements. It has been proved beyond doubt, that light as well as other factors (strychnine poisoning, heat, faradization) produce an acid reaction of the retina and that acids in their turn are able to provoke a contraction of the cones. Hence, it may be concluded that the local condition that gives rise to the pigment migration is the formation of acids. These acids, however, can be produced by various means: by direct illumination, by changes due to nervous influences, and, finally, by local and general humoral changes.

The influence of light as well as of the

general humoral conditions is not restricted to the retina. Light, as is well known, has a definite effect on the central nervous system, affecting the level of its basic tonus, which is, of course, also under the influence of the humoral conditions present in the body.

In the light of these conclusions we should consider all experiments concerning the pigment migration induced by other stimuli than light—that is, the various reflex movements—reported in the introduction, and the movements due to various drugs (cocaine, santonine, adrenalin).

Finally, as to the pathway by which the central nervous system exerts its influence, it seems to me, in accordance with the reported experiments in which the optic nerve had been severed, that the old conception of Engelmann is justified, that the optic nerve contains centrifugal, retinomotor fibers. This conclusion is contrary to that at which Shoko Kyo, a Japanese author, arrived on the basis of his experiments, which are reviewed in the *Zentralblatt für die gesamte Ophthalmologie*.²² He states that in frogs in which the optic nerve had been severed unilaterally, faradization as well as the application of drugs which produce a migration of the retinal pigment have the same retinomotor effect on both eyes. He does not believe, therefore, that the retinomotor impulses are transmitted through the optic nerve. I am unable to say to what this difference in the findings is due, all the more since Kyo's paper was accessible to me only in the review mentioned. In another paper Kyo²³ reports the results of experiments in which he has studied the effects of a great number of drugs on the pigment migration of the frog's retina. His conclusion is that drugs, stimulating the central nervous and the sympathetic nervous system, cause a migration of the retinal pigment, while

drugs having the opposite effect on the nervous system do not influence the retinal pigment. This, according to my experience, does not apply to naphthalene.

The author is greatly indebted to Dr. Ralph E. Miller of the Department of Pathology, for his generous help. The histological sections were excellently done by a technician on the staff of Dr. Miller's laboratory. Dr. Adrian Kameraad, of the Department of Biology, was kind enough to make the microphotographs reproduced in this paper.

SUMMARY

Experiments with strychnine and naphthalene have shown that the retinal pigment of dark-adapted frogs shows light position when the animals are poisoned with strychnine, and that in light-adapted frogs poisoned with naphthalene the retinal pigment assumes dark position.

From this the author concludes that there is a regulating influence of the central nervous system on the position of the retinal pigment.

In frogs, in which the optic nerve on one side was severed, the drugs did not influence the eye operated upon. The author concludes that the pathway through which the central nervous system exerts its influence must be located in the optic nerves, supporting Engelmann's theory of the existence of centrifugal, retinomotor fibers in the optic nerve.

The position of retinal pigment appears to be influenced by the following factors: (1) the basic tonus of the central nervous system; (2) the "light tonus" of the central nervous system; and (3) local humoral conditions due to the influence of light and various general metabolic factors.

DISCUSSION

DR. FREDERICK H. VERHOEFF (Boston): I should like to ask the essayist whether or not he has excluded the pos-

sibility that cutting the optic nerve has affected the retina in such a way that it will not respond. If you cut the optic

nerve, it affects the retina profoundly, for subsequently the ganglion cells disappear. I have always assumed that the effect was very great the moment you injured the optic nerve; that it was due to changes that take place, electrical and chemical, the result of the cutting, and that these changes cause impulses to pass backward along the nerve and injure the ganglion cells.

If the retina has been injured, of course, you would not expect it to respond to the action of a drug as does a normal retina.

Assuming, however, that this is not so, is it necessary for the essayist to assume that there are special nerve fibers going back into the retina?

We know if you stimulate any nerve, motor or sensory, impulses will pass in both directions. I think it was Head who drew attention to what he called antidromic impulses that pass backward along sensory nerves. Isn't it possible that in the optic nerve the fibers that ordinarily carry the impulses to the brain would serve the purpose for which the essayist hypotheticates special nerve fibers?

Then I should like to have Dr. Burian make a diagram illustrating his conception as to how nerve impulses passing to the retina affect the pigment cells. He may have several different ways to suggest.

DR. BURIAN: The first point brought out by Dr. Verhoeff, of course occurred to me, too. It is quite probable that the cutting of the optic nerve profoundly affects the eye; however, I thought that this, at least to a certain extent, could be paralyzed by taking the animals in various stages after the cutting of the optic nerve, or up to 20 days after the cutting of the optic nerve.

As to the retinal motor fibers, whether there really are retinal motor fibers or whether it is a question of conduction of the impulse both ways, I could not say;

for the experiments on which I am reporting do not explain this sufficiently. However, in view of Engelmann's experiments, which show that there is not only a direct influence from the brain to the eye, but from one eye to the other, we have necessarily to assume that there must be some kind of reflex arc and, therefore, afferent and efferent fibers and a center should be present.

DR. VERHOEFF: It doesn't seem to me that that follows. All that is necessary is for impulses to get back to the other eye.

DR. BURIAN: I can't quite see how the impulses would come from one eye through the brain, through the centers to the other eye, without having a special afferent fiber.

DR. VERHOEFF: It seems to me it would be very simple. Somewhere fibers from the two eyes go to the same place; otherwise an image from one retina could not be unified with one from the other retina. Hence impulses from one retina could be carried back to the other.

DR. BURIAN: My talk was not concerned especially with the retinal motor fibers. What I wanted to show most was that there was an influence of the central nervous system on the pigment migration. The way it is carried on is, I thought, by special fibers—or else by the same fibers, only with other impulses going the other way, and my experiments, unfortunately, don't give any answer to that.

DR. VERHOEFF: I take it that now you admit that your investigation does not prove the existence of special fibers.

DR. BURIAN: I still think as we usually do, that when there is a reflex action, there must be three elements.

DR. VERHOEFF: What we usually think isn't necessarily true.

DR. BURIAN: I didn't want to go into a criticism of the reflex action.

DR. VERHOEFF: Well, you brought it up!

DR. BURIAN: Yes, I did, but I don't think it is quite that way. I feel that the explanation that there are special fibers, is simpler than to assume that in the same nerve fiber the impulses go back and forth.

DR. VERHOEFF: It is more complicated to think there are two things, than one.

DR. BURIAN: Not necessarily, I think.

DR. VERHOEFF: It is to my mind.

DR. BURIAN: The third question I do not quite understand.

DR. VERHOEFF: You claim that there are these special fibers. I want you to draw a diagram of a retina and show how they act.

DR. BURIAN: I wouldn't be able to make a diagrammatic drawing of the effect of the impulses on the retinal pigment.

DR. VERHOEFF: Roughly explain how you think the impulses act.

DR. BURIAN: The way by which they act?

DR. VERHOEFF: You say that the impulses come to the retina and affect the pigment epithelium. We would like to have some idea just how they could do this. You must have some conception as to this because you think it possible. Just mention one way you think it could happen.

DR. BURIAN: I don't have any special conception about that, about the mechanism of this effect; you mean, anatomically?

DR. VERHOEFF: You have that nerve impulse coming to the retina. I want to know what it does after it gets there.

DR. BURIAN: I have no special—

DR. VERHOEFF: I think it is rather difficult to assume the impulses if you can't think of any way they can act.

DR. BURIAN: There are probably various ways, but I brought out modestly the fact that this occurs. I haven't attempted

any explanation.

DR. VERHOEFF: That leaves it a little doubtful that nerve impulses are concerned in the matter. Perhaps the effects are produced directly from the blood.

DR. BURIAN: I think the important point is that it is not produced by the blood. We know from other pharmacological experiments that these two drugs, strychnine and naphthalene, affect a definite part of the central nervous system. There is no reason why suddenly, in this case, these drugs should affect by way of the blood.

DR. VERHOEFF (interrupting): You don't mean to say that the retina isn't part of the nervous system, do you?

DR. BURIAN: Oh, yes, that is right.

DR. VERHOEFF: Why couldn't that be affected directly?

DR. BURIAN: It still wouldn't be by way of the blood. You see, the nerve endings are also part of the nervous system, and are not directly affected by strychnine and naphthalene.

DR. VERHOEFF: You are sure they are not?

DR. BURIAN: In the case of naphthalene—

DR. VERHOEFF (interrupting): In the retina, you mean?

DR. BURIAN: I wouldn't have any way of checking that in the retina. The influence of strychnine, we know, in man is not peripheral—or do you think so?

DR. VERHOEFF: I don't know, as concerns the retina. You are the one trying to tell us that.

DR. BURIAN: Not in man.

DR. VERHOEFF: I want to know how conclusive your evidence is.

DR. BURIAN: I don't know whether there is anything else.

DR. VERHOEFF: I haven't anything else in mind.

DR. BURIAN: Thank you.

A CONTACT-LENS-TELESCOPIC SYSTEM*

JEROME W. BETTMAN, M.D., AND G. STUART MCNAIR
San Francisco

Attempts have been made for centuries by the use of innumerable optical devices to help those unfortunate individuals who have suffered a drastic and permanent reduction of visual acuity. In 1646, Kircher designed a hand telescopic spectacle for near use. Dixon, in 1785, constructed a telescopic spectacle from two spherical mirrors, which were later replaced by spherical lenses. In more recent times, Hertel and Von Rohr developed the familiar Zeiss telescopic spectacle. The Hamblen Company of England and Feinbloom of New York likewise devised telescopic spectacles. The Feinbloom type is designed on the anomophotic principle: magnification in the horizontal meridian is $\times 1.8$, while in the vertical meridian it is only $\times 1.3$. With this type an image magnified $\times 1.8$ is seen at a distance which seems to approach more nearly the actual distance.

The ordinary types of telescopic spectacles are large, heavy, and conspicuous. The patient's field of vision is restricted to a dangerous degree. Many ophthalmologists have reported that most of their patients who can secure improvement in visual acuity in no other way cannot be persuaded to wear the telescopic lenses in public. Even the nearly blind are vain about their personal appearance and the restricted visual field is both an annoyance and a hazard.¹

To overcome these difficulties we conceived the idea of producing a telescopic spectacle by using a contact lens for the eyepiece and a highly convex ophthalmic lens for the objective. The appearance of such an arrangement is only slightly

more objectionable than that of the ordinary cataract lens. The field of vision is larger than with the ordinary telescopic spectacle of $\times 1.8$ magnification, with which the visual field is reduced to 24 degrees.

A search of the available literature revealed the fact that the theoretical possibilities of this arrangement had been suggested by Dallos² and Boeder;³ however, neither of them tested the principle in actual practice.

Before proceeding with the description of this telescope, let us briefly consider some of the properties of telescopic spectacles in general. All telescopic spectacles are constructed on the Galilean principle, a positive objective and a negative eyepiece separated by the difference of their focal lengths. This practice is followed because:⁴

1. Galileo's is the only system in which two simple lenses produce an erect image. Other telescopic systems need an erecting system which makes them thicker and heavier and results in additional loss of light (4 percent at each glass-air surface).
2. In other telescopic systems the lenses are separated by the arithmetic sum of their focal lengths, not their difference; therefore, the telescope must be longer.
3. The Galilean type of telescope produces less astigmatism with a large flat field than do other types of telescopes.
4. Galilean telescopes have a large exit pupil.

The following simple formulas govern the construction of a Galilean telescope:

$$\frac{F1}{F2} = \text{magnification}$$

Where $F1$ = focal length of the objective lens, $F2$ = focal length of the eyepiece.

The lenses must be separated by the difference between their focal lengths, that is, $F1 - F2 = D$.

The following simple principles must

* From the Department of Ophthalmology, Stanford University Medical School.

be followed in the construction of a telescopic spectacle:⁵

1. The telescope must be of relatively low magnification, otherwise the speed of movement of objects and the reduction of visual field is not tolerable.
2. The interpupillary distance of the telescopic spectacle must equal that of the wearer. If it does not, the symmetry of the visual field and the definition of the image are impaired.
3. The frame must be absolutely rigid so that tilting of the spectacle around the antero-posterior axis cannot occur. When a telescopic spectacle is tilted, the periphery of the optical system is brought into use. This results in increased chromatic aberration and astigmatism.

The patient for whom we devised this contact-lens-telescopic system was unable to wear an ordinary telescopic spectacle. The unsightliness of the telescopic spectacles was a grave handicap in his search for employment even though his vision was improved from 8/200 to 20/100 +1 by them.

As far as we know the only type of telescopic lens previously designed to overcome the impairment of visual field and the unsightliness of the usual telescopic spectacle is that advocated by Berliner.⁶ The lens that Berliner described was designed by Polackoff and developed by the Univis Company. It consisted of strong positive and strong negative flint lenses of a high index of refraction separated by a Crown glass component of a low index of refraction—all components being permanently fused together. This solid-glass telescope was then set into a carrier lens mounted in an ordinary spectacle frame. The Univis type is definitely an advance over the customary type of telescope, but is certainly not so inconspicuous as one would desire.

The contact-lens-telescopic system here described was designed to be as inconspicuous as possible and to allow the patient to use his entire visual field. A contact lens served as the eyepiece, and

a biconvex lens in a spectacle frame was used as the objective. To avoid undue separation between the spectacle (objective) and contact lens (eyepiece), it was apparent that the effective diverging power of the contact lens must be as great as possible. Only then could an objective (spectacle lens) of high power and short focal length be used, so that both the desired magnification and the short distance between the objective and eyepiece would be obtained.

A few examples will serve to emphasize this: A simple telescope with a magnification of $\times 2$ was constructed by Eggers⁷ by using a +5.00 diopter objective and a -10.00 diopter eyepiece separated by the difference of their focal lengths, 10 cm. If a +10.00 D. objective and a -20.00 D. eyepiece had been used, the separation would have been only 5 cm.

The cornea acts as a converging lens of approximately 45 diopters because of its convex curvature. A contact lens eliminates the cornea as a refracting medium. The converging power of the contact lens, which depends upon the curvature of the corneal segment of the contact lens, is substituted for that of the cornea. Consequently, we decided to use a contact glass on which an entirely flat surface had been ground, as this would optically eliminate the cornea as a converging lens. In other words, the cornea, which acts as a strong converging lens, could be optically neutralized. Therefore, the same effect would be produced as when a strong minus lens of a dioptric power equal to that of the cornea is held in front of the eye. Our patient's corneal curvature was found to be 44 diopters with the keratometer; consequently, with this eliminated by the flat-surface contact lens, the effect produced would be that of a -44 diopter lens. This, then, would serve as the minus lens (eyepiece) of a Galilean telescope. One would then expect

a magnification of $\times 2$ with an ordinary $+22$ diopter lens (objective of the telescope) set in a spectacle frame 27 mm. from the eye (the difference of the focal lengths of the two lenses). To reduce the cosmetic disfigurement, a stronger plus lens, a $+29$ biconvex lenticular, was used at a shorter distance from the contact lens (18.5 mm.) with approximately $\times 1.6$ magnification. With this combination of lenses, the patient was able to read 20/100.

The contact glass was ground on the principle of the Dallos contact glass.⁸ In this type of glass the optically effective region of the corneal portion is only the central 8 mm. This permits the grinding of a much higher correction on the contact glass without excessive increase in weight or thickness of the glass. In our contact glass the optically effective portion was restricted to 6 mm., on the anterior surface of whose corneal segment a flat surface was ground. The posterior surface of the corneal segment was made sufficiently concave just to clear the cornea, as is the case with an ordinary contact lens. The scleral curve was that which fit with the greatest comfort (again as with the ordinary type of contact lens). The optically effective portion was restricted to 6 mm. instead of 8 mm., as in the Dallos contact glass, in order to facilitate grinding without increasing the weight of the glass. Observation of the patient's pupil showed that it did not dilate over 4 mm. under ordinary conditions; therefore, a 6-mm. corrected corneal portion was sufficient. The weight of the finished contact lens is 0.6 gm. instead of the usual 0.5 gm., is thoroughly comfortable, and has been very satisfactory.

The objective lens for distance was a $+29.00$ diopter lenticular type, biconvex lens set in a very rigid frame made of zylonite and metal. A metal bridge and pad arms were used to obtain an exact

adjustment and rigid fit. The pad arms were especially made from solid gold stock, tempered to the proper hardness. This was necessary because of their unusual length of 19 mm.

As mentioned above, the patient is able to read 20/100 with this contact-lens-telescopic system, without experiencing vertigo or excessive chromatic aberration. A plano balance was placed in the spectacle frame before the uncorrected eye so that the patient might have the advantage of a large field (vision in this eye was 6/200). No diplopia nor confusion was caused by leaving this eye open. No attempt was made to correct the poorer eye with the same type of telescope.

In the Zeiss telescopic spectacle the reading addition is placed on the front of the object lens. The standard reading addition is a $+4$ lens. The magnification obtained with this reading addition is $\times 1.8$, the same as that obtained with the distance portion. A $+8.00$ D. reading addition gives twice the magnification of the distance portion, 2 times 1.8, or $\times 3.6$. To read newspaper print fairly well without further magnification in the reading addition the patient's distance vision with the telescopic lens should be about 20/50. If it is less than this the reading addition should be greater than a 4-diopter lens so that further magnification is obtained.⁹ Thus, a patient with 20/100 vision with a distance telescope should have a $+6.00$ D. reading addition. This is done to supply a magnification of $\times 1.5$ for reading besides the $\times 1.8$ magnification that he already has for distance. Thus, a total magnification of $\times 1.5$, 1.8, or 2.7 is available for reading. The reading distance, depth of focus, and visual field are reduced with further increase in the magnification; therefore, additional magnification for reading should not be prescribed unless it is necessary.

The visual acuity of our patient was

20/100 with this telescopic system. Accordingly, we decided to use a +6.00 D. addition for reading. A +35.00 D. biconvex lenticular lens, incorporating the +6.00 D. addition with the +29.00 D. objective, was mounted in another spectacle frame similar to the one described above. The finished spectacle is shown in figure 1.

Fig. 1 (Bettman and McNair). Spectacle of the contact-lens-telescopic system showing long pad arms.

With this the patient could read Jaeger 1 with some difficulty at a distance of 13.5 cm. He was able to read 48 words of ordinary size newspaper print a minute. With his Zeiss telescopic spectacle and +8.00 D. reading addition he was able to read only Jaeger 2 and 35 words per minute. The cosmetic improvement can be seen by comparing figures 3 and 4.

For those who may wish to prescribe the contact-lens-telescopic spectacle described, the following outline of procedure may be of value:

1. Determine the refractive error.
2. Measure the corneal curvature with a keratometer.
3. Try on contact lenses of the ordinary type from a trial set to determine the correct scleral curvature and to be certain of the clearance of the corneal segment. The radius of curvature of the cornea may also be determined from Obrig's table.¹⁰
4. A contact lens of the Dallos type with a 6-mm. flat anterior surface and the posterior corneal and scleral radii determined in step 3 may then be ordered. Should the patient's pupil be larger than 4 mm.,

the flat surface of the contact lens may have to be somewhat larger.

5. A convex lens of approximately one half the dioptric power of the corneal curvature (which has been optically eliminated by the contact lens) should be placed before the eye with the contact lens in place. The distance between the contact lens and the objective lens must be approximately the difference between the focal lengths of the objective lens and the eyepiece (contact lens). The optimum distance between the objective and eyepiece and the power of the objective are somewhat modified by the magnification desired, the refractive effect of the fluid meniscus between the contact lens and cornea, and any existing spherical ametropia of the eyeball.³ The details can be worked out with a trial set.
6. A biconvex, preferably lenticular, lens is ordered and placed in a very rigid frame. The nose pads are built up to hold the lens at the required distance from the contact lens.
7. The optical center must be adjusted to coincide precisely with the center of the patient's pupil. The slightest variation will blur the image.
8. An objective lens for reading equal to the power of the distance objective lens plus the reading addition required is then mounted in a frame similar to the one used for the distance objective lens. A 4.00 D. addition is sufficient if no magnification other than that given by the distance telescope is needed (that is, if the distance vision is 0.5 or better with the telescope). Stronger reading additions to produce greater magnification may be used as required.

It is wise to test the patient with a telescopic lens of the usual type from a trial set, to be certain that substantial improvement in vision will be obtained, before he is subjected to the expense and time necessary to obtain a contact-lens-telescope.

Case history. J. G., a white male, aged 50 years, was first seen in October, 1936. He had had no difficulties until two years before entry, at which time his vision failed gradually. His general health had always been excellent.

Examination: Vision was R.E. 7/200; L.E. 8/200; but no Jaeger for either eye. Both eyes were normal externally.

Fundi: White raised areas of fibrous-like tissue in the macular regions were seen in both eyes. That in the right eye was: 1 by 1½ disc diameters in size (fig.

Fig. 2 (Bettman and McNair). Photograph of fundus of patient's left eye showing raised, white, tumorlike mass in macular area. This eye was corrected to vision of 20/100+ and Jaeger 1 with difficulty by using the contact-lens-telescopic system.

2); that in the left eye, 2½ by 4 disc diameters. One small superficial hemorrhage was present at the edge of the area in the right eye. The fundi were otherwise normal. The tension also was normal, as were the ocular rotations.

Retinoscopy: R.E. +.25 D. cyl. ax. 180°; L.E. +.50 D. sph. = +.50 cyl. ax. 120°

Visual fields: Absolute central scotomata were present in each eye with a 1.5-mm. white object on the Walker screen at one meter. The scotomata extended irregularly between the 5° and 20° circles in each eye. The peripheral fields were normal.

The general medical examination uncovered no pathology.

Laboratory examination: Blood, urine, blood Wassermann, and spinal fluid were negative.

Impression: Disciform macular degeneration.¹¹

Telescopic lenses of the Zeiss type were fitted from a trial case. The following lenses resulted in the vision indicated:

O.D. 0 Base Zeiss × 1.8 with -50.
D. sph. 20/200

O.S. 0 Base Zeiss × 1.8 with -50.
D. cyl. ax. 60° 20/100 +1

Add O.D. +8.00 —Jaeger 16

O.S. +8.00 —Jaeger 3

(The above was prescribed for the left eye only.)

In August, 1937, the patient returned having the same vision with the telescopic spectacles as when they were prescribed. He had been able to use the lenses successfully. However, the unsightly appearance of the spectacles and his inability to see without them had caused his application for several jobs to be rejected. The reduction in visual field was annoying to him. Accordingly, the procedure outlined above was carried out and the following contact-lens-telescopic spectacle was prescribed for the left eye.

Eyepiece: 2/7.5 Dallos-type contact lens with flat anterior corneal surface 6 mm. in diameter.

Objective lenses: Biconvex lenticular, +29.00 D. sph. for distance, +35.00 D. sph. for reading.

The *mounting* consisted of a special rigid metal frame with nose pads built up.

With this combination the patient was able to see 20/100+ in the distance and could read Jaeger 1 with some difficulty. His visual field for distance was no longer restricted. The lens looked far less conspicuous than the usual telescopic lens, although not so inconspicuous as an ordinary spectacle. The patient experienced no untoward symptoms such as color aberration, vertigo, or headaches. He has but little difficulty in keeping his place

Fig. 3 (Bettman and McNair). Patient wearing Zeiss telescopic spectacles.
 Fig. 4 (Bettman and McNair). Patient wearing contact-lens-telescopic system.

while reading, as was demonstrated by his ability to read 48 words of ordinary newspaper print per minute.

Several improvements or alternatives in the telescope described may at once strike the reader. To produce a thinner lens the objective may be ground from high-index lead glass. However, such a glass would not weigh less, and would scratch more easily. A bifocal objective spectacle may be conceived but a +6 or 8 D. addition would hardly be practical. The need for exact adjustment of the pupillary distance of each segment would further increase the difficulty. It also occurred to us that instead of a flat surface, a concave surface might be ground on the corneal segment of the contact lens in order to yield a stronger eyepiece. This was discarded as impractical because accumulation of lacrimal secretion in the concave portion would probably destroy the optical effectiveness, and such a lens

would be most difficult to grind.

The contact-lens-telescopic system is indicated in the same types of visual impairment as is the ordinary telescopic lenses. In those patients whose vision is permanently reduced from high myopia or a macular lesion they are most useful and satisfactory.

SUMMARY

A method for constructing a telescopic spectacle by using a contact lens with a flat corneal segment as an eyepiece and a strong positive lens in an ordinary spectacle frame as the objective has been described. The patient for whom this contact-lens-telescopic system was prescribed was able to see as well at distance with it as with his Zeiss telescopic lens, and was able to read better. The cosmetic disfigurement was much less than with the Zeiss telescope and the field of vision was not restricted.

VITAMIN THERAPY IN OPHTHALMIC PRACTICE

JOSEPH LAVAL, M.D.

New York

Much has been written about the importance of vitamins in general medicine, and three reviews have appeared in ophthalmic literature. It must of course be realized that much of what follows will be only suggestive and show certain trends and indications as to the uses of the various vitamins in ophthalmic practice. Definitely positive statements and findings will be infrequent, but some general conclusions will be self-evident.

VITAMIN A

This vitamin is best associated in our minds with cod-liver oil and recently with haliver oil. It is present in good amounts in eggs, butter, milk, cream, and such dairy products. A deficiency of this vitamin manifests itself clinically first, as night blindness (hemeralopia) and later as xerophthalmia. Recently, dark-adaptation tests in early and beginning A avitaminosis have been advocated, but as yet they are not sufficiently standardized to warrant positive statements. It has been

shown that the visual purple of the retina after exposure to strong sunlight regenerates slowly in the eyes of rats on a diet deficient in vitamin A (Fridericia and Holm) and it has also been proved that the normal retina is rich in vitamin A (Holm, also Yudkin, Kriss, and Smith). Vitamin A has been used to cure xerophthalmia and the hemeralopia due to depletion of vitamin A with, of course, brilliant results, as witness the cases of the fishermen of Labrador as reported by Aykroid, and the cases of the natives of the Philippine Islands reported by Gamboa. However, vitamin A has been used for the hemeralopia due to retinitis pigmentosa with no improvement at all, as was reported by me in 1933 (Levine).

Vitamin A is being used also in the conjunctival sac with massage into the cornea in cases of keratitis dystrophica, but the results are variable. Some authors report brilliant results, others no improvement. In the writer's own experience there were some cases in which it seemed to do

much good, others in which irritation and aggravation of the symptoms resulted.

In certain cases of blepharitis and conjunctivitis in children there is no doubt that malnutrition is a factor, and here large doses of cod-liver oil are beneficial. Pillat reports the changes in Chinese eyes as a result of vitamin-A deficiency and mentions night blindness, dryness of the conjunctiva, Bitot's spots, xerosis, and even keratomalacia, meibomitis, hordeolum, and blepharitis. Vitamin A is also of use in phlyctenular keratoconjunctivitis and other related conditions of scrofulous origin. In women a low-grade chronic conjunctivitis with mild photophobia may be due to A avitaminosis as a result of dieting in the effort to keep a streamlined figure. Langdon described the case of a young woman who used no butter, eggs, or milk and had a corneal dystrophy which cleared up on the administration of cod-liver oil.

When depletion of vitamin A is advanced, changes in the lacrimal gland result with diminution and even entire loss of lacrimation. Mori showed that these changes in the lacrimal gland were responsible for conjunctival changes in xerophthalmia, which then gave rise to the corneal changes. Yudkin, in similar experiments, drew different conclusions as to which lesions arose first, but Wolbach and Howe demonstrated that all the changes are due to a replacement of the columnar epithelium by stratified squamous epithelium going on to keratinization.

In diabetics there may be an increased demand for vitamin A, as certain experiments by Ralli *et al* showed. In depancreatized dogs (artificial diabetes) it was found that definite corneal epithelial changes occurred of the same type as in vitamin-A deficiency. These corneal changes were prevented by feeding cod-liver oil to the depancreatized dogs. Ap-

parently, in these diabetic animals the demand for vitamin A is increased.

VITAMIN B

This vitamin is found in such foods as meats, potatoes, and green vegetables, but is most concentrated in yeast. It has various complex components the most important of which are B₁, the antiberi-beri component (thiamine), and B₂ or G, the antipellagra portion (riboflavin), the absence of the latter causing cataracts in rats. However, for clinical purposes it is to be remembered that concentrated yeast tablets as marketed by any of the reliable pharmaceutical firms contain B₁ and B₂ in high amounts. (For a complete study of the vitamin-B complex see the article by E. M. Nelson in the *Journal of the American Medical Association*, 1938, v. 110, Feb. 26, no. 9, p. 645.)

In the *Archives of Ophthalmology* for December, 1934, the writer reported a case of bilateral acute optic neuritis with marked diminution of vision associated with pellagra. (It is known that the peripheral neuritis of pellagra and of beriberi is due to the lack of vitamin B₂ and B₁, respectively.) In this case the pellagra and optic neuritis both were cured, even though alcohol was taken in fairly large amounts daily, because yeast was administered in large doses, thus supplying the necessary quantity of vitamin B₂. In a case of toxic amblyopia due to alcohol, recently observed, vision was improved from hand movements to 20/20 for each eye in a period of two weeks by administering vitamin B₁ and B₂ in the form of yeast tablets, even though some alcohol was taken daily. Carroll reported the same results in a series of cases in 1937, and the present writer quoted Shastid's experience with cases of optic neuritis cured by vitamin B₁ and B₂. In all cases of retrobulbar neuritis, toxic amblyopia, and optic neuritis—whether due to nasal-sinus

infection, alcohol and tobacco, or multiple sclerosis—it would seem advisable to use concentrated yeast tablets to supply large amounts of vitamin B₁ and B₂.

Similarly, in cases of incipient cataract the same therapy should be carried out, for riboflavin (anticataractous for rats) is present in the concentrated yeast tablets. Furthermore, there is sulphur in these yeast tablets (HS-cystine), and some connection between the sulphur content of fish lenses and the prevention of human cataracts has been reported by Shropshire. A further connection between cystine and the formation of galactose cataracts in rats has also been shown; this will be discussed under vitamin C.

VITAMIN C

This vitamin is found in the citrus fruits—orange, grapefruit, lemon, and lime. The pure crystal in the form of cevitamic acid has been prepared.

According to Bellows and Rosner, "In normal eyes the lens and aqueous are rich in vitamin C, in the cataractous lens the amount of vitamin C is diminished or entirely absent, and the aqueous of an aphakic eye contains only a slight amount of this substance. Experiments were performed which showed a definite reduction in the vitamin-C content of the blood in persons with cataract. Furthermore, vitamin C is absorbed from the conjunctival sac into the anterior chamber. Presumably this takes place through the cornea." These investigators also proved that the substance in the lens which reduces a special dye (sodium 2, 6, di-chlorobenzene-indophenol) is entirely vitamin C, and not any other reducing substances such as sulphhydryls. Bellows went still further and showed that the cataract produced in the albino rat by lactose (Mitchell and Dodge, Mitchell and Cook) and by galactose (Yudkin and Arnold) is due to a loss of the sulphhydryl content

of the crystalline lens which can be delayed by cystine and to a lesser degree by vitamin C in this type of cataract. Accordingly, it would seem that in cases of incipient cataract vitamin B₁ and vitamin B₂, to supply the cystine, and also vitamin C should be administered. In the writer's own practice this procedure has been carried out for the past four years, but of course no conclusions should be drawn as yet.

Bietti believes that the decrease in the amount of vitamin C in the aqueous and in the cataractous lens is the result of the lens changes and not the cause. He was unable to prevent or influence naphthaline cataract by administering vitamin C.

In 1932 Szent-Györgyi and Svirbely in Hungary proved that hexuronic acid is vitamin C. At the same time King and Waugh of the University of Pittsburgh showed that a crystalline compound which they isolated from lemon juice was identical with hexuronic acid. Szent-Györgyi found that the best source of vitamin C was the peppers grown in Hungary. However, patients with purpura were relieved by the juice of peppers or of citrus fruits but not by the pure crystalline vitamin C. On further investigation it was found that citrus fruits and the peppers contain a second substance controlling the permeability of capillaries and this substance is called vitamin P. The symptoms of scurvy seem to be due to a lack of both vitamin C and P.

Accordingly, it would seem advisable for ophthalmologists to utilize the juice of citrus fruits in large doses in attempting to control intraocular hemorrhage whether due to trauma (operative or other) or to some metabolic disease such as diabetes. Yudkin recently advocated the same therapy and seemed quite encouraged by its results. The present writer has also tried it in several cases of intraocular hemorrhage, both postoperative

and metabolic, and feels encouraged enough to continue with its use.

VITAMIN D

The use of vitamin D in ophthalmology has been limited to cases of myopia in the hope that this vitamin plus calcium would cause an increase in the amount of calcium in the sclera and thus prevent further stretching. Recently the writer reviewed this subject and gave the results of clinical experiments which showed no favorable influence on myopia after vitamin-D therapy. However, it should be borne in mind that the prescribed dosage of 10 minims daily may have been insufficient. Inasmuch, however, as this is the dosage for cases of rickets we may assume that it is sufficient for cases of myopia investigated clinically. The use of vitamin D in keratoconus has also been suggested.

SUMMARY

It is suggested that in cases of the following vitamin deficiencies it might be

theoretically valuable to prescribe the following treatment:

1. Vitamin A—Prescribe a tablespoonful twice daily in cases of poor dark adaptation, phlyctenular kerato-conjunctivitis, photophobia, and low-grade conjunctivitis in women who are on a slenderizing diet or in cases of other corneal and conjunctival lesions in which the history shows a lack of vitamin-A intake.

2. Vitamin B (B_1 and B_2)—Prescribe eight yeast tablets daily of the brewers'-yeast type put up by any of the reliable pharmaceutical firms, or the powdered form may be ordered. This is to be used in cases of incipient cataract, in optic neuritis, retrobulbar neuritis, and also in toxic amblyopia.

3. Vitamin C—Order the juice of at least two large oranges or one grapefruit daily in cases of incipient cataract. (This is plus the brewers' yeast which is also to be taken daily.) In cases of intra-ocular hemorrhage order the juice of four lemons daily.

136 E. Sixty-fourth Street.

LECTURES ON MOTOR ANOMALIES*

V. DEVELOPMENT AND COURSE OF STRABISMUS

A. BIELSCHOWSKY, M.D.

Hanover, New Hampshire

The answer is, that the result of the therapeutic procedures depends to a high degree upon the kind of retinal correspondence that is present in the individual case. The prospect of restoring binocular single vision by correcting the faulty position of the eyes will, of course, be much better if the normal correspondence has been proved to be intact. Further, most ophthalmologists will recall patients with alternating squint who had never noticed diplopia but suffered tremendously from it after the squint had been corrected or reduced by operation. The diplopia in some of these cases is a paradoxical one; that is, the distance between the double images points to the difference between the present and the former position of the eyes. Thus, for instance, a patient whose convergent squint of 25 degrees had been reduced to a convergence of 5 degrees will see crossed double images of about 20 degrees; or, if a divergent squint of 30 degrees had been reduced to 5 degrees, will see homonymous double images of about 25 degrees. Sometimes the diplopia disappears after a few days due to a reestablishment of suppression. In other cases the diplopia can be very persistent and cause a good deal of trouble to the patient as well as to his doctor, who might be reproached by the patient for not having told him before the operation about a possible diplopia afterwards. One can prevent such an unpleasant situation by ascertaining whether or not anomalous retinal correspondence has developed dur-

ing the period of squinting. In repeated examinations (which must be made in any case where an operative procedure seems to be necessary), many patients, if tested with afterimages, will find to their surprise that they no longer see the afterimages separated from one another but as forming a cross. This will indicate that the anatomic substratum of normal retinal correspondence, although present, is not functioning under the ordinary conditions of seeing, in which the substitute is more convenient. But in a dark room, where the patient sees nothing but the afterimages, the dormant normal correspondence has a better chance to arouse and maintain itself against or beside the anomalous correspondence. Of course, in using the afterimage test one must avoid any influencing suggestion. The patient must be told, before the beginning of the test, only that he will see a vertical and a horizontal afterimage of the glowing filament and that he must carefully watch the position of both lines relative to each other so that he may be able to reproduce it by means of a simple drawing. If these conditions are fulfilled the result of the test will be unequivocal.

In cases of alternating squint one should not fail to ascertain how the eyes react to simultaneous stimulation of both the foveae by means of the phorometer or, better still, of the haploscope. If simple drawings, such as a circle and a square, respectively, are presented to either eye separately, the drawings will be fused or will cover each other, provided the correspondence functions normally. But in some cases it is very difficult or even impossible to make the patients see both images situated on the

* From The Dartmouth Eye Institute, Dartmouth Medical School. Read before the Seventh Annual Mid-Winter Clinical Course of the Research Study Club, Los Angeles, California, January, 1938.

maculae at the same time. They will see only one of the images either with the right or the left eye, the other image being suppressed (alternating uniocular vision). By shifting the image in the squinting eye, particularly in the vertical direction, it can more readily be brought to the patient's consciousness and it may remain visible for a while if it is now slowly brought toward the macula. But it will disappear before it has reached the latter and, if the shifting is continued very slowly, it will suddenly appear beyond the second image, or below or above it. Occasionally the images may even be made to touch or partly overlap, but one will not attain fusion or a perfect covering of the two images. This peculiar behavior can be explained only by assuming that the patient changes the angle of squint, instinctively trying to find a position in which the images would not be situated on corresponding retinal points, because two identical macular images localized in the same direction without being fused may, in the case under discussion, cause such an uncomfortable feeling that the patient, without knowing it, endeavors to avoid it by changing the angle of squint. To ascertain this behavior before any operation is performed is very important. For, in such cases there will very probably be a disturbing diplopia after the squint is removed or reduced to a minimum. Usually it disappears sooner or later. But one cannot tell how long the diplopia will last in the individual case. Therefore one ought never to omit discussing this possibility with every patient having alternating squint who shows symptoms of anomalous correspondence, and particularly the unsteadiness of the angle of squint just described, which would suggest the phenomenon of horror fusionis. The appearance of this phenomenon depends not unconditionally on the existence of an anomalous correspondence. I have also

seen it in cases in which the double images corresponded perfectly to the small angle of squint that had remained after one or several operations. Horror fusionis may be due to a defective development of the sensorial apparatus in the occipital lobes. In such cases there is neither a normal nor an anomalous but no sensorial correspondence at all because the two eyes of the patient do not present the halves of a single organ, Hering's "Doppelaugen," but two organs which, in regard to the sensorial apparatus, are independent of each other. But such cases, I am sure, are extremely rare. Horror fusionis may be produced by a protracted disuse of one eye, or arise due to a severe nervous shock, and the fusion faculty may be capable of being developed by proper training and a most careful removal of anything that may cause a difference between the visual function of both eyes.

Passing on to the development and the course of the different kinds of strabismus, I am going to discuss, first, the most frequent and, with regard to the therapeutics, the most important form; that is, convergent squint. It arises, as a rule, in early childhood. Only in a small percentage of the cases does it begin after the sixth year, following a disease or injury reducing the vision of one eye; sometimes it is due to a protracted occlusion of one eye, if it had been bandaged for a couple of days. I have seen some cases of this kind, one of them in a boy of 14 years who came to our clinic some time ago because of a chalazion in the right upper lid. After the extirpation the right eye was bandaged for two days. When the eye was uncovered he complained of diplopia. There was a manifest convergent squint of 18 degrees. The double images were uncrossed and their separation subtended exactly the objective angle of squint. He had a hyperopia of 5 diopeters, which had never been corrected, since

the boy had full vision of both eyes and had never noticed any trouble previously. His brother had been operated on for permanent convergent squint two years before. Even after atropine had been given and the refractive error had been corrected the deviation did not disappear. But when the retinal images were shifted from the disparate to corresponding points by means of prisms or the haploscope there was fusion with depth perception; in addition, an unusually high amount of aniseikonia was determined by Professor Ames. The images of the two eyes could be equalized by meridional size lenses of 8 percent axis 90 degrees before the right and 6 percent axis 180 degrees before the left eye. The patient had binocular single vision when he wore before each eye a combination of $+4.00$ and 10^{Δ} , base out, with an aniseikonic correction in a temporary frame. After three days he reported that he had broken the glasses which were in the left side of the trial frame, but nevertheless he had binocular single vision when wearing just one set of glasses before the right eye. I found the convergent squint reduced from 18 degrees to 5 degrees. The aniseikonia was likewise reduced considerably. There was still spontaneous diplopia but, in order to get binocular single vision he needed only 2^{Δ} , base out, before each eye in addition to the hyperopic correction. After three days he discarded the glasses, since he had found that he had binocular single vision without them. When examined he showed an esophoria which, after suspension of fusion, became manifest and gradually increased up to 9 degrees with and without the glasses correcting the hyperopia. Vision was 20/15 with and without the glasses.

The case is a very instructive illustration of the different factors which have been discussed as being responsible for the development of squint and particularly of the decisive role played by the

fusion apparatus in the etiology of squint. The combination of three important etiological factors—namely, inherited disposition, excessive accommodation induced by hyperopia of more than 5 diopters, and a considerable esophoria based on an anomalous position of rest—brought about neither a permanent nor even a periodic convergent squint as long as it was counteracted by the fusion apparatus in the interest of binocular single vision. But why did the fusion apparatus fail to overcome the tendency to squint for a considerable length of time after the bandage had been removed from the right eye? Since the correction of the hyperopia did not reduce the angle of squint more than a few degrees, it is evident that in this case the excess of accommodation was an etiologic factor of less importance than the convergent position of rest which, according to the results of later examinations, amounted to 9 degrees; that is, half the angle of the convergent squint which was found after the removal of the bandage. The other half is to be attributed to an excessive convergence innervation due, very likely, to so-called diplopiaphobia. It is not unusual that a person, noticing double images for the first time and trying to fuse them without success, will find instinctively that the double images are less disturbing if their separation is increased. The only voluntary innervation which may serve that purpose—by altering the position of the eyes relative to each other—is the convergence innervation. Whether or not diplopiaphobia plays such an important role in the etiology of squint as some authors (Duane, van der Hoeve) believed, is still an open question. In my opinion a convergent squint is to be attributed to diplopiaphobia only in a comparatively small number of cases. Our patient's convergence spasm subsided gradually when about half of the deviation was compensated for by means of prisms. The re-

maining half was overcome by the patient's powerful fusion apparatus. Without going into details of this most interesting case, I just want to mention the fact that the high amount of aniseikonia that was found during the period of convergent squint decreased almost exactly in proportion to the decrease of the deviation. At present, as soon as the latter is again evoked and brought up to the previous amount by an adequate haploscopic arrangement, a corresponding increase of the meridional aniseikonia is reestablished.

The results to be expected from a rational treatment in cases in which convergent squint has arisen relatively late, are much better than in the other group because of the existence of a fully developed normal retinal correspondence. Of course, the attainment of the ideal result, the restoration of binocular single vision depends also in these cases on the vision of the squinting eye. If an existing amblyopia can be improved, fusion exercises by means of the phorometer or the haploscope or other orthoptic apparatus will, in such cases, have the very best chances, sometimes even without any operation; for instance, in cases in which an original esophoria had been transformed into a manifest convergent squint in consequence of an occlusion of one eye. In the main group, patients with a convergent squint existing since early childhood, the ideal result—namely, binocular single vision—can be obtained in only a much smaller percentage of the cases. That is due partly to the frequent amblyopia of the squinting eye, partly to a persistent anomalous correspondence or a deficiency of the fusion apparatus, either congenital or acquired in earliest childhood, so that very frequently one must be satisfied with the removal of the cosmetic disfigurement. The earlier the squint can be treated the better the prognosis. By bandaging the fixating eye for weeks or

months a considerable improvement of the vision of the squinting eye may be achieved if the amblyopia is not of an organic but of a functional origin. The second task in such a case—a careful correction of any refractive error is presupposed—would be to overcome the suppression tendency of the squinting eye. To accomplish this the child must be at least three years old or more, so that it can tell about the double images and the images seen in the stereoscope or amblyoscope. It is not very difficult to find out whether the position of the double images relative to each other is due to an anomalous or to the normal retinal correspondence. In the latter case one may try to obtain fusion by means of prisms; Sattler reported very gratifying results in this way even when he had to prescribe prisms up to 20^A for either eye. Their strength can be reduced after some weeks or months if fusion is obtained. If not, suppression and amblyopia of the squinting eye will return unless the occlusion of the dominant eye is continued.

In cases of a constant deviation of more than 20 (arc) degrees, when a complete relaxation of accommodative effort, first by means of atropine, then by a full correction of hyperopia, has failed to bring about any improvement in the condition or has removed only a small fraction of the deviation, an operation must be considered. As to the earliest age at which a child with a convergent squint can be operated on, definite rules cannot be given. The patient should not be operated on before glasses, possibly combined with prisms, have been worn for several months and the angle of squint has been found to be rather constant during repeated examinations. In quite a number of cases the squint decreases gradually and, while the children are growing, finally disappears, mainly because of the change of the topographic anatomic conditions which favor the tendency of the

eyes to diverge. As long as a decrease of the angle, even though it be small, can be ascertained, one should wait. But if an angle of more than 10 (arc) degrees is the same after six months of observation, or has possibly increased, I do not hesitate to operate on a child of about four years of age. The older the patients, the sooner an operation may be performed after the angle of squint has been found to be fairly constant in repeated examinations and after the nonoperative procedures have been tried without success. The prospects for these procedures will be better after the angle of squint has been reduced to a small fraction, provided that the amblyopia or a defective condition of the fusion apparatus does not present insuperable obstacles. There are cases in which binocular single vision and depth perception together with a certain amplitude of fusion sets in immediately and spontaneously after the operation. But in the majority of cases in which any good result is to be obtained at all, it takes some time until binocular single vision can be demonstrated after the angle of squint has been reduced to a residue of a few degrees by operation. Fusion training might help a good deal, but in the end it will depend on the condition of the cortical centers governing the fusion apparatus whether the functions of *perfect* binocular single vision, including depth perception and fusional amplitude, will be obtained or just fusion without depth perception or fusion only for near and not for distant objects because of a deficient fusional amplitude. These patients, as a rule, do not notice diplopia, availing themselves of the faculty acquired during the previous squint to suppress the images of one eye. The functional deficiency of the fusion apparatus can be improved by exercises only if it does not depend on a defective condition of its cortical centers. But even cases in which all the symptoms point to a con-

genital deficiency of the fusion apparatus may be cured by proper treatment, thus proving that they are functional anomalies, as in the following two examples.

A student, 20 years old, unusually ambitious and industrious, had been operated on three times by one of the most prominent ophthalmologists on account of a convergent strabismus that had arisen in earliest childhood. Seven weeks after the last tenotomy, diplopia developed to the great annoyance of the patient. He was a big, strong fellow, and apart from a very pronounced neuropathic habitus, perfectly healthy. Both refraction and vision were normal. There was a permanent convergent strabismus of 2 degrees for distance, but the double images were alternately homonymous and crossed, fluctuating greatly, up to an amount of 10 degrees. Apart from the convergent deviation the right eye was turned upward, the amplitude also fluctuating between 2 and 14 degrees, but the objectively measured vertical deviation always corresponding to the vertical separation of the double images. There was no sign of a parietic anomaly, the angle of squint being independent of the direction of view. All attempts with prisms and haploscope to get the double images fused failed, due to the continual changes of the angle of squint. Because of these conditions and in view of the very small deviation I doubted whether I should be able to relieve the patient of his diplopia; but since he insisted on my making a last attempt to remove his troubles I advanced his left external rectus, producing as an immediate result a divergence of 10 degrees. It decreased gradually and was finally transformed into a convergence of 2 degrees; that is, the same amount as before the operation. But the vertical divergence had disappeared and did not return. The horror fusionis remained, the patient saw now crossed, now uncrossed double images that could not be fused and were

annoying to such a degree that the patient after a month earnestly asked to have his original squint restored in order to be able to continue his studies. But I finally succeeded in persuading him to wait six weeks longer and to submit to regular stereoscopic exercises. Gradually, the fusion faculty was developed so that after six weeks the patient noticed double images only of small objects contrasting with the background, and at last acquired even a certain amount of depth perception. The ophthalmologist who supervised the exercises told me that during the exercises the patient always had to overcome enormous psychic inhibitions. He gave the impression as though he were actually looking for double images, but fortunately no longer found them.

This case is interesting in some respects. It confirms the experience gained in other cases of vertical divergence which, if they are due to intermittent nervous excitations should not be operated on, because they may disappear without any particular treatment if restoration of the fusion faculty can be achieved. It confirms the rule, the importance of which I have emphasized time and again that, in the face of apparent failures of squint operations, to the performance of which no objection could be raised, one must not be induced, in such cases, to precipitate procedures which would spoil the effect of the operation. One has to remind the patient that he must endure the troublesome condition for at least two or three months and that he must await the results of exercises. Finally, the case demonstrates that horror fusionis may not be caused by a congenital defect but may be due to a neurotic disturbance and can be cured even if it has existed for years and in spite of the various kinds of treatment that have been tried unsuccessfully.

Another extremely interesting case of

horror fusionis was demonstrated by me at the meeting of the New England Ophthalmological Society in January, 1935, and was published in my article on "Congenital and acquired deficiencies of fusion" (*American Journal of Ophthalmology*, 1935, volume 18, October). The case has, in my opinion, a fundamental significance. The patient, who had been operated on several times on the lateral as well as the vertical ocular muscles because of a complicated squint, showed a slight deviation composed of a lateral, a vertical, and a torsional component, changing with the slightest alteration of view because of a paretic weakness of almost all the muscles of the right eye. There was, according to the direction of gaze and the position of the head, homonymous or crossed diplopia with positive or negative vertical divergence and conclination or disclination of the vertical meridians. Even for one and the same direction of gaze the deviation was very unsteady, due to spasms of the convergence and the vertical divergence innervations. Fusion could not be obtained by any method. Only after an unusually high amount of aniseikonia had been determined, and corrected by size lenses, could binocular vision with depth perception and a certain fusional amplitude be established. Aniseikonia has to be looked for in every case of weak or defective fusion because it may be an important etiologic factor, not only in so far as it involves an incongruence of the ocular images (such as ametropia or other conditions impairing the visual acuity), but because it may produce anomalous and nervous irritations as well as a weakening of the physiologic fusion mechanism, either in its sensorial portion by favoring suppression, or in the motor portion by checking the fusion innervation, on account of a mental antipathy toward the fusion of heterogeneous ocular images.

PARALLEL STUDY OF THE PATHOGENESIS OF RHINOGENOUS OPTIC NEURITIS AND OF SEROUS IRITIS

BÉLA WALDMANN, M.D.
Oradea (late Nagyvárad) Roumania

In the last score of years, the American medical literature has subjected the question of retrobulbar neuritis to a thorough study, but it is evident that opinions as to the origin of this disease are still divergent.

In 1906 I was so fortunate as to be present at the meeting of the Society of Hungarian Oculists, before which Onodi demonstrated for the first time his world-renowned preparations. He made a very deep impression on his audience and aroused their profound interest in this problem. His address was of great interest to me, and under its influence, during the course of the last three decades, I have paid especial attention to all those cases that could be brought into causal connection with the accessory nasal sinuses. Thus I have acquired a considerable amount of data which have now encouraged me to essay the solution of the pending questions from my own experience.

The relation of single cases of iritis to the mucous membrane of the nose was first mentioned by Ziem in 1887; namely, he observed in three instances that the iritis underwent a considerable improvement upon treatment applied to the simultaneously existing rhinitis. Kuhnt denied the possibility of the causal connection, and attributed the improvement to the fact that the cauterization of the mucous membrane of the nose, in a collateral way, diminished the hyperemia of the uvea, and thus brought about the improvement. The conflicting opinion of this prominent ophthalmologist buried the question until the present day, although, as will be apparent from the following comments, it well deserves a careful study.

A. OPTIC NEURITIS

Before entering into the discussion of the pathogenesis, I shall describe some types out of my own collection of cases, selecting those that are apt to support my conception.

Type 1. M. L., a female, aged 46 years, consulted me on March 29, 1928, complaining that six days ago she had gone to bed with perfect sight and next morning, upon awakening, noticed that she saw nothing with her right eye.

Examination: No objective vision in the right eye; light perception good. Vision in the left eye 5/5. Both eyegrounds were wholly normal. Suspecting that this might be a case of hysteria, I made control examinations which, however, yielded a negative result. The nervous system was unimpaired; a blood test, negative.

Diagnosis: Neuritis retrobulbaris.

Rhinoscopy: No secretion could be seen on the right side on account of hypertrophy of the turbinate. X-ray report was negative. Upon my strong recommendation next day the middle nasal turbinate was resected and the ethmoidal cells opened, whereupon abundant, purulent secretion was evacuated from all their sections and even from the sphenoidal recess. Subsequent to the operation vision rapidly improved and, after the lapse of two weeks, became completely normal.

Comment: In the present case the X-ray report was of no avail, and although vision had been rapidly reduced to the minimum, the eyegrounds displayed nothing abnormal. This form presents the most favorable prognosis, visual recovery taking place in a fairly short time.

Type 2. S. E., a female, aged 36 years, called on me on January 4, 1928, with the complaint that her sight in the left eye had abated during the last few days.

Examination: Vision in the right eye 5/5, in the left 5/30; in the left fundus the outlines of the papilla were indistinct, the blood vessels tortuous.

Diagnosis: Intraocular optic neuritis; that is to say, a mild papilledema. The nervous system was unimpaired; blood test, rhinoscopy, and X-ray studies were negative. Notwithstanding, I daily placed cocaine-adrenalin swabs into the left nasal meatus. Although this procedure resulted in the continuous evacuation of a pro-

fuse, muco-purulent secretion, vision nevertheless gradually became so reduced that on the 28th of January the patient could only count fingers from a distance of half a meter. Then I urged the opening of the ethmoidal cells, and it was found that the mucous membrane of the left ethmoidal sinus showed polypoid degeneration. From the day of the operation the sight gradually improved and on the 18th of April it had become 5/7. Four years subsequently the same process was repeated in the other eye, following a similar course.

Comment: From this case, which represents the moderately severe form, the lesson can be drawn that the failure to obtain results by applying swabs by no means disproves the rhinogenous origin of the neuritis, but, on the contrary, in such instances an operation is urgently indicated.

Type 3. M. I., a female, 21 years of age, consulted me on December 22, 1937, complaining about considerably impaired vision in her left eye.

Examination: Right eye unimpaired; in the left fundus the papilla was greatly elevated (3 D.), its outline wholly blurred, but the filling of the blood vessels scarcely deviated from the normal.

Diagnosis: Papilledema in a high degree. Vision from a distance of 2 meters is ability to count fingers. The blood test was negative; rhinoscopy revealed the presence of abundant purulent discharge in the middle meatus. I suggested to the patient to have her nose treated, but owing to the approaching Christmas holiday she refused to do this and went home. In five weeks' time she again appeared, her vision having diminished to counting fingers at half a meter, and the optic nerve was by way of becoming atrophied. She refused to undergo treatment at this time also.

Comment: This case represents the most serious form of optic neuritis; namely, one in which the elevation of the disc is pronounced. The fibers of the optic nerve are very sensitive to pressure and quickly atrophy.

PATHOGENESIS

It is unnecessary to mention in detail the pertinent American literature, and I shall therefore confine myself to enumerating only those authors whose writings have been accessible to me; namely, W. L. Benedict, E. Campbell, C. Crane, S. Gifford, L. White, and the medical staff of the Johns Hopkins Hospital under the direction of A. Woods. Although these writers have brought the very best of

their knowledge to the clearing up of this question, yet according to the results of H. Campbell the opinions are so contradictory that they may be conducive to considerable confusion in the reader. Some authors regard the disease of the optic nerve to be a septic focus originating in the teeth or the tonsils. A considerable number of ophthalmologists hold that the provocator is the collateral edema, and there are only a few who take for granted that the source of the affection is in the pressure conveyed through the thinned bony separating wall. The assumption that the inflammation in the canal is brought about by the direct spreading of the infection from the sinus has most adherents. This thought gained strong support in the discovery of Herzog, according to which the medullary cavities in the bony wall of the accessory sinuses lead directly towards the mucosa, likewise towards the dura mater, and thus provide a direct path for the passage of the causative agents. Hajek also concurred in this concept of Herzog, but in my opinion this cannot be applied in cases of optic neuritis, but only in those of serous iritis, and for the following reasons:

First: If pathogenic agents were to penetrate into the optic canal, their propagation would not be restricted to the canal, but they would migrate farther either into the brain or into the eye, where they would provoke an inflammation such as we generally see at postmortem examinations of those cases of serous iritis and sympathetic ophthalmia in which the uveitis of the fellow eye was preceded by an optic neuritis, as was shown by the animal experiments of the younger Velhagen. To my knowledge no mention has been made in the literature of such an instance of optic neuritis of rhinogenic origin followed by uveitis.

Second: In optic neuritis the pathogenic agent could not even migrate from the diseased sinus, for in my cases, as also in those under the observation of Campbell and Gifford, rhinoscopy often established a diagnosis of chronic hypertrophic inflammation, or empyema. In these cases the strepto- and staphylococcus, and, according to the finding of James J. Moore, even the *Bacillus pyocyaneus* may be encountered in the accessory cavities. Against this peril the organism raises a defense, preventing the escape of these dangerous pathogenic agents into the canal by forming a defensive wall; for otherwise most individuals suffering from empyema would die of meningitis. According to Hajek the edema in such cases is restricted only to the upper strata of the mucosa, while the rest down to the periosteum become transformed into a coarse, fibrous connective tissue. White histologically examined nine cases and similarly found a fibrous thickening of the mucosa which sometimes involved even the bone. According to my own observations, this is a dam that is impervious to the pathogenic agents; therefore, they cannot play a role in bringing about neuritis, and the whole process may be regarded as aseptic.

Thus, in bringing about optic neuritis the following two factors may play a part: either direct pressure, or collateral edema.

In a closed empyema it is easily possible, that in connection with the disintegration of the mucosa and its purulent necrosis, gases of decomposition develop that may be conducive to the tightening of the bony wall. If the latter is thinner than normal and at the same time the abnormal course of the canal brings it nearer to the sinus, the rise of pressure in the cavity may be directly conveyed through the bony wall to the soft tissues in the canal. Thus these may suffer compression and give rise to the various

grades of neuritis: (a) in mild compression, retrobulbar neuritis (normal fundus); (b) in moderate compression, intraocular neuritis; (c) in compression of a higher degree, papilledema.

The clinical symptoms of the cases I have described indicate the existence of these three grades.

Besides the enumerated American authors, the role of the collateral edema has been corroborated also by Traquair, Letchworth, and recently by Sakaye Kitahara, who says that in the neighboring formations this is produced by the purulent imbibitions of the sinus. To this edema can be traced those cases in which the deterioration of vision sets in suddenly; similarly rapid, also, is its return, as was noted in my case, type 1. An edema may appear in such a short time, but not the disturbance caused by the intrenched pathogenic agents.

By the aid of roentgenograms, L. White established the existence of canals of different gauges; in general, the calibers were of 4 to 6 mm., and from this he drew the conclusion that canals of narrower caliber are more apt to promote the occurrence of neuritis than those that are wider. Apart from the fact that the roentgenograms of the accessory cavities, in general, are disappointing, I consider White's conclusions to be erroneous, for the fluid in the intervaginal cavity compensates for the 1 to 2-mm. difference, the space of the canal being filled in every instance. Thus the pressure exerted upon its wall, or the edema occurring in it, in the same way creates a narrowness of space, whether its caliber is 4 or 6 mm. Besides, Endre Luzsa* on the basis of numerous screening examinations states that roentgenograms taken of one and

* State Eye Hospital, Budapest; Director, Professor Imre.

the same canal at different planes may display various dimensions, because an infinitesimal change in the position of the tube, of the film, and of the skull is apt to influence the outlines of the shadow, and therefore we cannot obtain absolute values. For this reason I shall not follow White's advice—namely, that nasal treatment is superfluous in the case of canals of 5 to 6-mm. diameters—because according to him, the optic nerve is not endangered, and spontaneous recovery can be awaited without risk.

From the foregoing it can easily be explained why rhinogenous optic neuritis is so rare, although the inflammation of the accessory cavities is of frequent occurrence. This is emphasized by several authors as a counter-argument to the theory of those who believe in the rhinogenous origin of single neuritises; namely, that for the development of an optic neuritis, two conditions are necessary: first, the abnormal thinness of the bony separating wall; second, an anomaly in the course of the optic canal which brings about a closer relationship between the optic nerve and the adjacent sinus,** and thus direct pressure, or the evolution of a collateral edema becomes possible. As the simultaneous presence of these two anomalies may be regarded as rare, accordingly also optic neuritises connected with them are strikingly rare, but this does not justify a doubt as to the existence of this pathologic form. Thomson also acknowledges optic neuritis to be a relatively rare disease, but he accentuates its great importance, requiring quick and energetic treatment.

Thus it is not justifiable to omit or postpone the treatment of the accessory cavities because in some cases the condition

healed spontaneously. According to Hajek, a partial or entire impediment to the evacuation of the secretion forms one important cause of the chronicity of the sinus affection. In this the composition of the secretion is significant, for according to him a thick discharge may be impeded even if the efferent duct is fairly wide. It is no wonder, therefore, that in optic neuritis, in the presence of a closed empyema, radical operation in the nose must often be performed because the swab had proved unsatisfactory. This was realized in my example of type 2, which, on the other hand, was under my constant control during the latter 10 years and in spite of the fact that optic neuritis occurred on both sides, no symptoms of multiple sclerosis were present. On the other hand, Meller believes that if, subsequent to an optic neuritis, a multiple sclerosis should make its appearance, even after the lapse of some years, the previously established rhinogenous origin could not be doubted at all.

The detrimental result of procrastination is vividly illustrated in the following data, compiled by Tibor Bajkay in 1937, from the Budapest Oto-Rhino-Laryngological Clinic. They operated upon 54 patients for retrobulbar neuritis, in 29 of whom there was a positive rhinological finding. In every one of these the posterior sinuses had been opened. Of those with positive rhinological findings, 5 fully recovered, 21 improved, and 3 remained uncured. Of the number of those with negative findings, 4 were cured, 15 improved, and 6 remained uncured. It was furthermore well established that patients who presented themselves 3 to 4 days after deterioration of the vision had set in, achieved full sight, whereas for those who presented themselves only after 8 to 14 days, the operation resulted in only an improvement. The nine patients whose condition was not improved by the operation,

** On the occasion of Onodi's demonstration I saw four such preparations in which the optic canal ran a course in one of the posterior sinuses to a length of 6 to 10 mm.

presented themselves for treatment after a lapse of two weeks.

Among their data a contralateral case was also described, in which a rightsided ethmoiditis gave rise to the occurrence of a retrobulbar neuritis on the left side and in two weeks, subsequent to the cleansing of the sinus in question, the eye healed with full vision. An anatomical preparation, corresponding to this case, was among the slides demonstrated by Onodi, which I had the pleasure of seeing.

S. R. Gifford in a relevant discussion writes: "In spite of the floods of ink that have been spilled on this question during the past 10 years, it is still decidedly a question and may be resolved into three principal parts: In what percentage of cases of retrobulbar neuritis is sinusitis the cause? Can retrobulbar neuritis be caused by the disease of the sinuses giving no evidence on rhinologic or roentgenologic examination; if so, what is the pathology of the disease of the sinuses? In the presence of retrobulbar neuritis with no apparent cause and with no nasal evidence of sinusitis should one advise exploratory operation on the sinuses?"

In regard to the first question I believe that the relevant statistics are not conclusive, because there is yet no consistent decision as to the rhinogenic origin of neuritises and therefore as many statistics are compiled as there are points of view upon which they are based. Suffice it to say that neuritis of rhinogenous origin is a rare disease, but that it does occur.

To the second question I can give an answer on the ground of my own cases. In every such case, when per exclusionem the origin of an optic neuritis can be located only in the accessory cavities, there is the possibility of a closed empyema even if the nasal and X-ray findings are negative. Therefore, in such instances—and this is the answer to the third ques-

tion—the explorative opening of the posterior sinuses is imperatively necessary.

B. SEROUS IRITIS

In 1929, 10 cases of serous iritis came under my observation, and by chance I found that a nasal swab soaked in cocaine-adrenalin solution was apt to bring about a striking improvement. I dealt with this topic at length in an article which appeared in the *Zeitschrift für Augenheilkunde* in 1930. This publication did not provoke much comment, and for this reason I again call the attention of ophthalmologists to this important fact. Prior to entering into the explanation of the pathogenesis, I shall describe various types from the cases I have observed.

Case 1. S. N., a female, aged 68 years, called on me on May 1, 1928, with the complaint that for one week her right eye had been inflamed.

Examination: There was an explicit serous iritis in the right eye; the fundus was invisible. The left eye was normal. A blood test proved negative.

Some weeks previously she had had a cold. The described ocular condition persisted with unvaried intensity for three weeks, associated with tormenting headaches, and at this time a mild iritis supervened also in the fellow eye, preceded, two days previously, by a neuritis. Because of the tendency of the pupils to dilate I dropped seopolamine into both eyes once a day only. Then I told the patient to consult a rhinologist, who established the presence of a chronic rhinitis and deviation of the septum. On the left side the nose proved normal. On the right side I applied cocaine-adrenalin swabs daily, whereupon the inflammatory phenomena as well as the precipitates, likewise the tormenting headache, showed a quick and striking improvement, and by July 8th both eyes had recovered with full vision. Meanwhile, when the precipitates disappeared and the fundus could be examined, a markedly developed optic neuritis could be observed in the primary eye also.

Comment: As will be seen from the description, in the primary eye a serous iritis made its appearance, followed later by an optic neuritis, and after the lapse of 25 days serous iritis supervened also in the other eye, having been preceded, by some days, by an optic neuritis. The fact that the condition of the primary eye in spite of the customary treatment gradually deteriorated until nasal treatment was begun,

and that from this time on a striking recovery was set in motion, and also that the torturing headache abated, authorized me to designate this bilateral iritis as of rhinogenous origin. For it is plain that the abatement of the severe symptoms, the elimination of the precipitates, and regression of the optic neuritis cannot by any means be attributed to the once daily administered scopolamine solution, but could be ascribed to the nasal treatment.

Case 2. H. E., a female, aged 22 years, had had a cold some weeks previous to her calling on me on the 14th of November, 1928.

Examination: Right eye normal; in the left eye a severe serous iritis.

Atropine was prescribed to be administered five times daily. The tuberculin test was negative; the blood Wassermann test positive.

Nasal finding on the 28th of November: rhinitis on the left side. These tests lasted for 14 days, during which time the condition of the eye, in spite of the energetic atropinization, gradually became worse, violent headaches supervened, and the precipitates greatly increased. Then, encouraged by the good results achieved in the first case, I resolved to try, instead of an antisyphilitic cure, treatment of the patient with only cocaine-adrenalin swabs. This resolution was prompted by an older statement by Römer, in which he said that even in case of positive blood test every iritis need not be regarded as syphilitic. The cocaine-adrenalin treatment was successful, inasmuch as after a few days the pains abated and the inflammatory phenomena of the eye considerably subsided, so that by the 28th of December I was able to examine the eyeground, which proved to be unimpaired; vision was 5/10. At this time the inflammatory symptoms were only moderate. In 10 days, however, the patient returned with the surprising statement that a few days before, the other eye also had become inflamed, while the condition of the primary eye was aggravated. Upon my interrogating her, she confessed to have neglected the nasal treatment for several days, in view of the improvement that had set in.

Examination: Well-developed serous iritis bilaterally with copious precipitates. Temperature 37.4°C. Nasal finding: The rhinitis present on the primary side displayed a vigorous recurrence. With adequate nasal treatment and with the administration of atropine both eyes recovered with full vision by the 9th of April. After the disappearance of the precipitates the eyeground examination, carried out meanwhile, showed both papillae to be intact.

Comment: From this description it is clear that in an individual, strongly syphilitic, a bilateral serous iritis supervened in an interval of several weeks, and in spite of the omission of antiluetic treatment, tamponade of the nose led

to a complete cure. It is a striking circumstance that inflammation supervened in the other eye only when the patient, at the time when there was considerable improvement of the primary eye, neglected the nasal treatment—as superfluous—and in this way the rhinitis became exacerbated. As, however, the optic nerve remained unimpaired during the entire duration of the disease, I would conclude that in the present case the transmigration of the pathogenic agents was by way of the ciliary nerves.

Case 3. T. M., a girl of 15 years, suffered in September, 1928, from a bad cold in the nose with copious secretion. Some weeks later, when these symptoms had passed, the right eye began to be inflamed, and in three weeks the left eye also. She came to consult me on the 6th of December, until which time she had had no treatment whatever.

Examination: Well-developed serous iritis on both sides with abundant precipitates. Vision in the right eye was reduced to the ability to see hand movements, and in the left eye to the ability to count fingers at a distance of one meter. The girl was poorly developed, her skin pale. Twelve of her 13 brothers and sisters had died. The Wassermann test was positive.

Rhinological findings: Rhinitis chronica et sinusitis ethmoidalis on the right side. In the present case—for the sake of comparison—I entirely omitted the treatment of the nose and besides the administration of atropine I confined myself to applying antiluetic treatment. From the time of admission until the 11th of March she received 18 injections of bismuth and 8 of salvarsan. In spite of this the precipitates, forming a mass on both corneae, scarcely diminished, although the inflammatory symptoms of the eye subsided. As the antiluetic treatment, carried on for 90 days, proved to be of very little avail, I stopped it and instead commenced the tamponade of the nose, the more so as meanwhile epistaxes occurred. Upon the application of this method the dwindling of the precipitates was accelerated, so that by the 20th of April the vision in the right eye had risen to 5/20, of the left eye to 5/15. It could now be seen that both papillae were normal. The patient was obliged to leave for family reasons, taking with her adequate instructions for steam inhalations.*

Comment: As can be seen from this case the antiluetic treatment continued for 90 days influenced the healing of the eyes only negligibly, whereas a striking success followed nasal treatment continued for 35 days. It can, therefore,

* A pot of 300-400 c.c. capacity is filled with boiling camomile-tea solution, and covered with a paper funnel, the tip of which is fitted into the nostril.

be stated that serous iritis, even in the presence of a strongly positive Wassermann test, also may be of rhinogenous origin.

Case 4. B. L., a female, aged 35 years, consulted me on November 3, 1937, on account of dim vision in her left eye.

Examination: The right eye was normal; the left eye entirely devoid of inflammation, with bulbar conjunctiva white, the cornea sound. However, in the aqueous chamber, scarcely noticeable, tiny precipitates could be observed.

Diagnosis: Cyclitis. Upon inquiry, she asserted that during the last 15 years she had received antiluetic treatment on several occasions; and that now for one week she was again being treated. Under the circumstances I did not think of a rhinogenous origin. As, however, the eye became strongly injected on the next day, the precipitates increased, and the inflammatory symptoms of the iris displayed during the course of the next 10 days a gradual aggravation, I insisted on rhinoscopy. The presence of a subacute rhinitis of the left side was found. For this reason, I forthwith applied cocaine-adrenalin swabs, a treatment that was conducive to the rapid subsidence of all inflammatory signs and the striking disappearance of the precipitates, so that within the following 10 days complete recovery ensued. According to the statement of the patient, the effect of the tamponade was to cause an abundant thick discharge to be evacuated from that side, through the nostril as well as posteriorly, which she had failed to observe up to that time.

Comment: Serous iritis broke out while antileptic therapy was in course of being administered. It gradually became aggravated in spite of vigorous atropinization; but upon the introduction of nasal treatment full recovery was effected within a short time.

Case 5. E. P., a female, 20 years of age, consulted me on the 5th of May, 1932, complaining of an inflammation of the right eye of a week's standing. I found a severe serous iritis, with copious precipitates. The patient was pale, emaciated, and the internal and screening examinations established the presence of an apical catarrh. Rhinoscopy revealed the presence of a severe rhinitis on the right side. As an experiment I ordered nasal tamponades, on the assumption that perhaps the presence of tuberculosis does not exclude the nasal origin of serous iritis just as had been the case in the presence of syphilis. I was not disappointed, for upon the administration of nasal treatment all the phenomena of the inflammation disappeared at an astonishingly rapid rate, and the patient regained full vision within eight days, by the 13th of May.

Comment: As is evident from this case, serous iritis may be of rhinogenous origin also in the presence of tuberculosis and independent

of the Koch bacillus. This I had declared to be possible as early as 1930.* My concept was corroborated by Löwenstein of Vienna (1936), who, on the basis of an experience of 35 years and of 34,000 examinations, made the statement that "the mere presence of the Koch bacillus does not necessarily indicate that it was the etiologic agent."

Case 6. A. K., a male, 24 years of age, was admitted on the 17th of November, 1937, complaining that his left eye had been inflamed for a few days and that previous to this he had suffered from rhinitis.

Examination: There was serous iritis of the left eye in the absence of lues and tuberculosis.

Rhinoscopy: A chronic rhinitis of the left side was found. Atropine and a nasal tamponade were administered, with but moderate improvement. By the 22d of December he had recovered completely. As soon as the precipitates had sufficiently disappeared, I examined him with the ophthalmoscope and to my surprise observed a moderate optic neuritis, which afterwards gradually regressed.

Comment: The importance of this case lies in the fact that only one eye was affected and yet optic neuritis appeared, which later wholly disappeared with the outstanding symptoms of iritis. It might be concluded that nasal treatment administered in time gradually stopped the reserves of the pathogenic agents migrating from the sinuses into the uvea. Thus the iritis extending to all three parts of the uvea began to regress even prior to the ascending neuritis having extended to the other eye through the lamina cribrosa. This is what took place in case 1, in which I began the nasal treatment only on the twenty-third day, when the fellow eye had become inflamed. Thus I observed—for the second time within 10 years—an ascending optic neuritis of the primary eye in connection with iritis.

It is therefore desirable that every serous iritis be subjected to ophthalmoscopic observation, and if this were done, perhaps my relevant observation will not continue to remain isolated in the literature.

On the other hand, the results in this sixth case indisputably point to the analogy between serous iritis and sympathetic ophthalmia.

I stated this analogy in full in 1937** and in order to disperse doubts I shall supplementarily report further data which I have recently discovered in the literature, and which I had not yet utilized in

* Zeitschrift für Augenheilkunde, 1930, and Archiv für Augenheilkunde, 1935.

** American Journal of Ophthalmology, 1937, v. 20, p. 618.

my writings. In chronological order A. v. Graefe was the first to give expression to the assumption that in a bilateral spontaneous uveitis the disease of the secondary eye supervenes under the influence of the primary eye.

Professor Schnabel, Vienna, 1902, one of the most prominent ophthalmologists of his time, who analyzed the pending questions of pathogenesis with an impartial and irresistible logic, rigidly adhered to the assumption that spontaneous uveitis and sympathetic ophthalmia are identical and denied the exclusive ability of injuries to bring about the latter disease. According to him sympathetic iridocyclitis as well as spontaneous iridocyclitis are produced by the same pathologic agent and in both of the latter this originates somewhere in the human body and reaches the uvea by the same route in both of these pathologic forms.

Elschnig, 1910, formulated his opinion on this subject, as described by Peters, as follows: "... and as regards the relation of sympathetic ophthalmia to spontaneous iridocyclitis, in this matter Elschnig repeatedly accentuated the identity. The simultaneous morbidity of the two organs is an evidence of its constitutional origin. If the two eyes succumb with a certain interval between, the inflammation of the secondary eye originates from the primary eye."

Finally, Meller in 1915 wrote as follows: "Idiopathic* uveitis is the same pathological form which we know of old as sympathetic ophthalmia. . . . Therefore, we should rather refrain from adhering too much to the term sympathetic ophthalmia, which we have failed to substitute with another term, up to the present, because without knowing the path-

ologic agent this is aimless."

After these preliminaries I hope it will cause no special inconvenience to the reader, if in dealing with the pathogenesis in one case I resort to the term "spontaneous iritis" and in another to "sympathetic ophthalmia," these two pathologic forms being identical; the difference between the two is only as to their etiology.

PATHOGENESIS

Serous iritis is an affection of a much greater importance than optic neuritis, on the one hand because it can be observed in a much greater number of cases than can the latter, on the other hand because it is often bilateral and therefore the neglect of adequate therapy is liable to result in a serious disability.

Ten years have passed since the publication of my first treatise, during the course of which I have had numerous cases of serous iritis under my care, and the conviction has grown upon me that this is a wholly separate affection that is caused by a specific agent and is independent of syphilis as well as of tuberculosis. In every case, two weeks prior to the affection of the eye, a catarrhal infection had occurred which ran a mild course and was confined chiefly to the upper respiratory passages, the patient being bedridden for only a day or two, if at all.

I was able as well to establish that in certain years only 1 to 2 cases occurred while in others 10 to 15, usually when a mild endemic influenza was prevalent in our city. My serous-iritis cases presented themselves, without exception, in the season October to April; accordingly I would call it a *seasonal disease*.** In this respect my opinion gained fresh reinforcement in the data of Broman Tore, according to whom 120 violent iritises

* The term idiopathic was used by Schirmer for those spontaneous iritises, the etiology of which is unknown.

** See American Journal of Ophthalmology, 1937, v. 20, 618.

occurred after 650 cataract operations (17 percent), making their appearance for the most part during the winter.

The excellent results achieved with nasal tamponade justify me in regarding serous iritis as of *rhinogenous origin*.

For this reason we should search for the causative agent in the accessory cavities. It is the influenza bacillus that is most often found in the accessory cavities, and due to its peculiarities it is apt to bring about serous iritis, as I showed in 1937.

Besides the Pfeiffer bacillus the *Diplococcus catarrhalis* has recently been brought to my attention.

In a publication from the Budapest First Surgical Clinic there appeared in 1938 a discussion of the bacteriology of the cavity of Highmore. From data derived from 50 cases, Dr. Szende and Dr. Murányi elaborated the findings in 26 chronic and 24 acute cases. In the discharge of the patients with chronic inflammations chiefly streptococci and staphylococci were found, while in the acute cases the discharge contained exclusively pneumococci and catarrhal diplococci in about equal proportions. According to these authors the greater part of their cases were of infections of influenzal origin. As, however, the openings of the antrum and of the ethmoidal sinus are in the same nasal passage, I am justified in presuming that these causative agents may be present in the latter also.

The pneumococcus cannot come into consideration, for, as is well known, this organism is apt to provoke much more serious changes in the eye than are seen in the manifestations of serous iritis. We must therefore turn our attention to the catarrhal diplococcus. This organism can be found on the mucosa of the nasopharynx even in normal conditions and according to the findings of the present writer it alone may be the causative agent

of an inflammation of the cavity of Highmore. Although its pathogenicity is slight, it is nevertheless capable of bringing about a catarrh of the upper respiratory passages. O. Seifert found it in the discharge of patients with a light bronchitis while R. Pfeiffer cultivated it from the deeper respiratory ducts as the causative agent of puerile bronchopneumonias associated with influenza bacillus. Thus the *Diplococcus catarrhalis* may come into consideration as bringing about serous iritis, either alone or associated with the Pfeiffer bacillus.

The question still remains as to how the causative agents reach the eyeball from the sinuses. In my opinion this can take place in two ways; namely, either by the hematogenous route, or by direct passage. The possibility of the former is verified by the known circulatory conditions; as to the latter the pathologic-histological findings offer sufficient evidence.

As I have previously mentioned, in the numerous cases of serous iritis observed by me the rhinological examination established, without exception, the acute catarrhal affection of the mucosa, or its exacerbation.

According to Hajek, when the sinuses succumb to acute catarrh, the mucosa, in its entire thickness, down to the bony wall is affected with an inflammatory edema and swells to three times its normal thickness. Within this, numerous smaller and larger cavities form which become filled with clotted serum, and the mucosa contains polynuclear leucocytes and lymphocytes.

According to this author a high degree of edematous inflammation in the presence of a relatively mild acute inflammation is a specific characteristic of the mucosa of the ethmoidal sinus. As a result, the inflammation extends relatively easily and speedily to the deepest layers of the mucosa, which acts as a periosteum.

In this sense, in the catarrhal affections of the sinuses (in contrast with empyema) no defensive dam of inflammation arises, and the lymphocytic infiltration can extend unchecked to the bony wall. It will not be hindered in its progress here either, for according to the previously mentioned discovery of Herzog, the medullary cavities of the bony wall provide a straight path for the etiologic agents toward the optic canal. Here it is easy for them to get into the pia mater and thence to settle down in the uvea.

It is thus readily believable that one of the chief factors in the cure of serous iritis is the treating of the nose, for when we insure an undisturbed drainage of the pathologic discharge of the sinus, we at the same time put an end also to the reserve of migrating causative agents. The resisting power of the attacked eye, supported by mydriatics, enables it to eliminate the remaining pathologic agents and recovery follows.

Hajek further writes: "That the rapid drainage of the discharge from a cavity is the most important requirement for a prompt recovery, is a universally valid basic rule of pathology."

Iritis serosa is in most cases unilateral, and the affection only infrequently makes its appearance on the other side also. This happens either some weeks later or may ensue after the primary eye has become blind, after a period of years. In the latter case Weigelin observed, subsequent to the removal of the primary eye, considerable improvement in the secondary eye, and the histological examination revealed a fresh inflammatory focus in the uvea, just as is the rule in sympathetic ophthalmia.

Serous iritis occurs more frequently than optic neuritis because the former, unlike optic neuritis, may supervene even in the presence of the thickest bony wall. In spite of this, just as in the case of the

latter, it is of less frequent occurrence than is the inflammation of the accessory cavities. The cause lies in the fact that for the development of serous iritis in addition to a catarrhal sinusitis another factor is also necessary—the condition that may develop in the uvea (in addition to constitutional factors) from an injury, or an unsuccessful operation, or an intra-ocular tumor.

According to the statement of other writers retrobulbar neuritis does not occur in juveniles, and I can allege the same as to serous iritis, for amongst the numerous patients under my observation there was none under 14 years of age. This means that both pathologic forms alike are related to the diseases of the posterior sinuses, which are not developed before the age of puberty. On this basis White's statement that optic neuritis is caused by disease of the antrum is in error, for this cavity has been shown to be present even in infants.

SUMMARY

As can be seen from the foregoing, the pathogenesis of optic neuritis and of serous iritis displays considerable differences; they have, however, many points in common.

The optic neuritis of rhinogenic origin is the outcome of an *aseptic process* going on in the optic canal, and is brought about exclusively by mechanical factors. Its origin is in the empyema of the posterior sinuses, or the chronic hypertrophic inflammation of the latter.

Spontaneous serous iritis, even in the presence of syphilis or tuberculosis, is in every instance the outcome of a *catarrhal infection*.

The source of infection is the catarrhal inflammation of the posterior sinuses, and pathogenic agents migrate directly from the sinus into the canal and thence, by way of the pia mater, into the uvea.

INTRAOCULAR TENSION IN ELECTROPYREXIA*

A PRELIMINARY REPORT

H. C. ERNSTING, M.D.

Cleveland, Ohio

There has been a most marked interest in electropyrexia within the past few years, but published data dealing with the effects of electropyrexia on the intraocular tension have not come to this writer's attention.

It was thought quite possible that an elevation of the intraocular tension might occur in electropyrexia and hence prove a contraindication to the treatment of those eye diseases (such as corneal ulceration, with the possibility of herniation or perforation of the cornea and glaucoma) in which such an event might prove disastrous. This study was therefore undertaken in an attempt to determine the effects of this type of artificially induced fever on the intraocular tension.

Neither the state of refraction nor the age has any appreciable effect on the intraocular tension. Holocaine has no influence on the intraocular pressure, though it does affect the cornea by producing "polygonal dry spots" which quickly disappear.¹ There are, however, many factors that may affect the intraocular tension, some of which are: certain drugs, external influences, action of the sympathetic and trigeminal nerves, action of the muscles, and so on.²

In electropyrexia or hyperpyrexia as induced by the Kettering Cabinet, it was found in the majority of 19 cases studied that the intraocular tension was definitely affected. The patients who were examined were suffering from various types of

arthritis and only two presented ocular pathology of any significance.

The procedure, prior to fever therapy, varied with the case to be treated. During fever therapy a sedative was given shortly after the temperature began to rise. The majority of patients received morphine gr. 0.25; some few received equivalent doses of pantopon or codeine, and an occasional patient received sodium amytal gr. 3. The dose was repeated, if the treatment was long or the patient became restless. The fluid level was maintained by the oral administration of 0.6 percent saline or, on rare occasions, of plain water. The average patient took between 2,000 and 2,500 c.c. of fluid per treatment. The rectal temperature was watched closely. Ice applied to the face and a fan situated near the head contributed somewhat to the patient's comfort. The duration of each treatment varied with the individual case.

Most investigators believe that the effects of artificial fever are unlike those of natural fever, but there are a few³ who report the effects to be quite similar. It is almost universally believed, however, that fever stimulates the development of immune bodies, favors phagocytosis, exerts an unfavorable influence upon the growth of certain bacteria, and diminishes the potency of toxins. Following a fever treatment, it is stated that the white blood cells are constantly increased. The polymorphonuclear leukocytes show a marked increase⁴ and there is a definite shift to the left in the Schilling hemogram. The red blood cells and hemoglobin do not show much change. There is a loss of

blood and tissue chlorides and of carbonic acid, and in patients who are subjected to prolonged treatment at high temperatures

this loss of acid ions induces some degree of alkalosis.⁵ This alkalosis may be controlled by the oral administration of 0.6-

percent saline solution and the inhalation of oxygen-carbon dioxide. The blood sugar, nonnitrogenous phosphorous, and serum calcium show little if any change. At the onset of treatment the systolic blood pressure may be elevated slightly, but after treatment it is lowered. During the maintenance period the basal metabolic rate is reported⁵ to be increased 5.5 percent for each degree (Fahrenheit) of temperature elevation. A marked increase in the number and size of the visible capillaries and the rate of flow has been reported, and it is said that this may be taken as a practical index of the circulatory changes that occur throughout the entire body during fever treatment.³

One would expect similar changes to occur in the eye, and the eye does present changes that may be attributed to the effects of hyperpyrexia. The conjunctiva becomes injected, and it is a question whether the fundus does not appear slightly more vascular. The intraocular tension, which was determined under holocaine anesthesia and by means of the

Schiötz tonometer, showed little or no change in 10 cases that were examined during treatment, but the tension, which was taken under the same conditions, 30 minutes after treatment showed a definite drop in the majority of the 19 cases examined (table 1).

CONCLUSION

No conclusions may be drawn from a preliminary report of this type. It is known that the intraocular tension generally follows passively the changes in general blood pressure. It is further known that the blood pressure may be definitely influenced by changes in the capillary system. In the majority of the 19 cases that were examined 30 minutes after fever treatment, the intraocular tension was lowered. It is evident that further study and investigation will be necessary.

I wish to express sincere thanks to the Department of Arthritis and Fever Therapy, whose courteous coöperation has permitted this work.

CAUSES OF BLINDNESS IN INDIANA

D. H. ROW, M.D.* AND C. D. CHADWICK**

Indianapolis, Indiana

The following report, based on the physical ocular examinations of 2,657 applicants for blind pension in the state of Indiana, gives a fair insight into the common causes of blindness in the mid-western part of the United States. The examinations were made by physicians practicing in or near the county in which the applicant resided, and the examiner was either an oculist or an eye, ear, nose, and throat specialist, as required by the Welfare Act of Indiana for 1936.

As a standard qualifying requirement, the central vision of the better eye of the applicant had to be reduced to 20/200 or less. All of the individuals included in this analysis were so handicapped. All applicants were adults. However, not all applicants were eligible for blind pension because of other considerations; usually financial support from other sources.

Through the coöperation of the National Society for the Prevention of Blindness, a standard form of the causes of blindness, prepared by the Committee on Statistics of the Blind, was obtained. Proceeding with this chart, which has a detailed cross-classification of topographical listings—such as, glaucoma, cataract, iritis, and corneal opacity—along its upper border, and etiological factors—such as, ophthalmia neonatorum, syphilis, trachoma, and diabetes—on the side margin, a topographical and an etiological factor was listed on each of the 2,657 individual records. After this was accomplished, it

was a relatively simple matter to enter the totals on the chart.

The analysis of these records is, for obvious reasons, inaccurate; for example, many of the applicants have been blind for years with secondary changes, such as cataract, developing after blindness, obscuring posterior disease. History of the applicant's loss of vision, in many cases, only confused the issue because of the usual lack of knowledge on the part of the applicant as to the real cause of his blindness.

Cases reported on the individual applicant's forms as cataract and glaucoma, were classified as glaucoma, since it seemed reasonable to consider the more profound and serious disease as the actual cause of blindness. Likewise, cases reported as senile cataract, but in which there was no light perception, were classified as posterior disease, without reference to the cataract.

Some applicants had lost one eye from injury or disease years before the loss of the second eye. Unless the question of sympathetic ophthalmia was involved, the loss of the first eye was not considered in compiling these figures on blindness.

Indefinite etiological classifications—such as, "probably syphilis"—were classified as "undetermined by physician," so that the incidence of syphilis in the final totals is probably underestimated.

Sympathetic ophthalmia was classified as uveitis, since the chart used had no listing for sympathetic ophthalmia. This is probably not so serious a deficiency of the record as is, at first consideration, imagined, for the factor of *post hoc propter hoc* comes into prominence when considering this disease, and without

* Consulting Ophthalmologist for Indiana Board of Industrial Aid for the Blind.

** Executive Secretary of Board of Industrial Aid for the Blind of the Indiana Public Welfare Department.

microscopic examination or even clinical observation of the active process of the sympathetic disease the diagnosis is often questionable.

Of all the etiological factors listed, probably the most accurate is trachoma, since the disease and its scar-tissue sequelae are superficial and quite characteristic.

Due to the frequent use of the vague term "senility" as an etiological factor,

this was added to the chart as the only deviation from the printed form of the Committee on Statistics of the Blind.

Because of the large and cumbersome nature of the original cross-classification chart, it has not been included with this report. The following two charts are self-explanatory. Chart 1 gives the numerical frequency of the local eye disease. Chart 2 gives the numerical frequency of the underlying etiology of the eye disease.

569	Etiology undetermined by physician	17	Tuberculosis
406	Senility	16	Systemic diseases, specified
321	Etiology unknown to science	14	Systemic diseases, not specified
226	Trachoma	11	Scarlet fever
160	Congenital and hereditary, not specified	11	Injuries, incidental to surgery
87	Syphilis, not specified	10	Ophthalmia neonatorum, gonorrheal
65	Injuries, not specified	9	Gonorrhea (excluding O.N.)
65	Vascular diseases	9	Syphilis, acquired
59	Infections, not specified	9	Typhoid
53	Infections, specified	7	Explosives, not specified
51	Diabetes	7	Street and traffic accidents
45	Ophthalmia neonatorum, not specified	6	Household activities
43	Hereditary and familial	4	Anemia and other blood diseases
42	Syphilis, prenatal	3	Birth injuries
37	Nephritis and other kidney diseases	3	Alcohol (methyl, wood, denatured, etc.)
33	Trauma (including burns)	2	Tobacco
31	Nonindustrial injuries, specified	2	Diseases of pregnancy and childbirth
30	Meningitis	1	Ophthalmia neonatorum
29	Toxic poison, specified	1	Septicemia
27	Toxic poison, not specified	1	Play or sport
26	Firearms	1	Industrial diseases (including poison)
23	Smallpox	1	Industrial injuries, not specified
21	Measles	1	Noninfectious diseases, central nervous system
21	Explosives, specified	1	Congenital and hereditary, prenatal
20	Neoplasms	1	Consanguinity
19	Etiology not specified		

NOTES, CASES, INSTRUMENTS

IODISM WITH SEVERE OCULAR INVOLVEMENT*

REPORT OF A CASE

H. KRIEGER GOLDBERG, M.D.

Baltimore

The purpose of this report is to record a case of bilateral edema of the lids and conjunctivae, bullous keratitis, and hypopyon secondary to iodine poisoning. Such severe ocular involvement is rarely observed.

M. F., a white woman, aged 68 years, was first seen at the Johns Hopkins Hospital in February, 1905. She complained of stiffness of the hands and feet. For a year she had experienced tingling of the right foot and a pain which radiated to her right hip from the right leg. She had had fleeting pains in her arms. Also, she had noticed that she could not differentiate coins or buttons when placed in her left hand.

Complete examination, supervised by Dr. Osler, showed only astereognosis of the left hand and moderate ataxia of both arms. Attention was drawn to the peculiar personality of the patient by Dr. Osler, but no details were stated. During her stay in the hospital she was given a saturated solution of potassium iodide. The initial dose was 15 min. and this was increased 2 min. every other day. After four weeks the iodide was discontinued because an iodide rash appeared on the extremities and face. Four days after discontinuing the iodides, the symptoms had entirely disappeared.

Following the patient's return to her home she continued to have "rheumatic" attacks and on her own initiative she took

potassium iodide in the same dosage that had been given to her in the hospital. After using the drug for any length of time she invariably developed a skin eruption over the face and extremities. Sometimes the eruption was macular and at other times it was pustular or vesicular. Cessation of the drug always resulted in disappearance of the rash. The patient noted that with each succeeding skin eruption, a shorter period of iodine consumption was necessary to produce the rash. She had not used the iodides for about one year until in February, 1938, she commenced taking 30 min. t.i.d. with increasing doses every other day. After three weeks a vesicular skin eruption appeared over the face, arms (figs. 1 and 2), and legs. However, on this occasion the patient persisted in the use of the iodide. On March 8th her eyes became painful and her vision failed rapidly. She again entered the hospital on March 11th, when her vision was reduced to light perception in both eyes.

OCULAR EXAMINATION

There was such edema and redness of the lids that they could not be opened voluntarily by the patient. The bulbar conjunctiva of the right eye was chemotic. The cornea was grayish and infiltrated. The iris was similarly discolored. The pupil was contracted, irregular, and adherent to the lens. There was a thin layer of exudate over the surface of the iris with loss of all normal luster and markings. There was a small hypopyon in the inferior angle of the anterior chamber. Tension was normal. The left eye presented a more advanced generalized chemosis. The cornea was grayish and hazy in color. Outlines of the pupil could barely be seen. There was a heavy

*From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University, Baltimore, Maryland.

exudate over the anterior surface of the iris and a large hypopyon half filled the anterior chamber. There was a definite loss of epithelium in a small area toward the 3-o'clock position which stained with fluorescein. Tension was normal. There

the center there were five or six small blebs which appeared to be on the posterior surface of the cornea and to arise between Descemet's membrane and the endothelium (fig. 3).

General physical examination was essentially negative except for the ocular and dermatological findings. The result of the neurological examination revealed the same ataxia of the arms and astereognosis of the left hand which had been found on her first admission. Her personality had not changed. She was inordinately proud of the fact that Sir William Osler had prescribed for her. This probably accounted for her continuing the prescriptions in spite of the repeated at-

Figs. 1 and 2 (Goldberg). Cutaneous lesions of face and arms on admission.

was a bare suggestion of red reflex in both eyes.

Vision was light perception with good projection in each eye.

There were a few bullae over the right cornea and several very faintly staining areas where there had probably been other recent bullae. On the left cornea towards

tacks of iodism. She definitely relished reciting the routine of her disability and her method of combating it.

The Wassermann reaction, blood gonococcal fixation test, blood chemistry, and blood cytology were entirely negative. Cultures taken from the bullae of the skin were sterile. The survey of various

systems was negative. Examination for iodine in the urine showed its presence in large quantities.

On March 11th, the day of admission, the patient was given instillations of atropine one percent t.i.d. and iodides were stopped. Immediately the patient made an unusual and rapid improvement. On March 12th the left cornea no longer stained. On March 15th the patient was able to count fingers at two feet with the right eye and the iris pattern was readily distinguished (fig. 4). On March 22d the vision was 20/200 in each eye. Nuclear sclerosis made it unlikely that further visual improvement could follow. The right eye was otherwise normal. The left eye at this time continued to show some folding of Descemet's membrane in the areas where the bullae had been observed. The skin eruption had entirely disappeared and iodine was no longer demonstrable in the urine. The patient continued to progress in an uncomplicated manner and therefore 14 days after admission she was discharged.

COMMENT

Swelling of the lids and conjunctiva is frequently observed after iodides have been prescribed.¹ Such symptoms may appear without an iodide rash appearing.

More severe ocular involvement has been observed. Lewin,² in 1899 and again in 1925, recorded retinal hemorrhages and corneal lesions resembling the bullae seen

Fig. 3 (Goldberg). Stereoscopic photographs of right and left eyes on admission. Edema of conjunctiva, cornea, and bilateral hypopyon are present.

Fig. 4 (Goldberg). Stereoscopic photographs of right and left eyes nine days later.

on the skin as resulting from the use of iodides. Hallopeau² in 1899 described a case in which bullae of the cornea appeared, the cornea became almost entirely opaque and the pupils were fixed to light and were irregular. Discontinuance of the drug was followed by disappearance of the lesions which reappeared when the drug was again prescribed. The case here reported, although similar to that of

Hallopeau, was even more severe. It would seem obvious that the ocular condition observed in the case here reported arose from lesions in the eye which were similar to those frequently observed in the skin. The hypopyon therefore resulted from the irritation of the corneal bullae which caused an irritative iritis and hence a sterile hypopyon.

SOCIETY PROCEEDINGS

Edited by DR. H. ROMMEL HILDRETH

MINNESOTA ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

SECTION ON OPHTHALMOLOGY

February 11, 1938

DR. WALTER E. CAMP, *president*

REPORT ON THE 15TH INTERNATIONAL CONGRESS OF OPHTHALMOLOGY AT CAIRO, EGYPT

DR. HENRY P. WAGENER, Rochester, Minnesota, said the recent International Congress of Ophthalmology differed from the meetings of most ophthalmological societies in that the major part of the scientific sessions were devoted not to discussions of ophthalmic surgery and therapeutics but to two phases of internal medicine which are closely linked to ophthalmology. The main subjects under discussion were hypertension and endocrinology, with especial reference to their ocular manifestations.

The ophthalmoscopic features and prognostic significance of the retinal lesions seen in cardiovascular renal diseases have been well established. The attention of the Congress was directed rather to the mechanism of development of these retinal changes. While Bailliart and Koyanagi incline still to the assumption of a direct action on the retina of a toxic product, presumably from the kidneys, most of the other speakers seemed to feel that the retinal circulation was involved primarily. It was recognized, however, that the lesions in the retina did not arise as a result of arterial or arteriolar sclerosis but through a dynamic disturbance of blood flow in the realm of pathologic physiology. There is still a lack of definite

proof and agreement as to the exact nature of this disturbance of blood flow. Thus, Volhard adheres strongly to his theory of ischemia; Mylius, of Hamburg, believes that passive hyperemia on the venous side is the predominant lesion, and Fritz, of Brussels, introduces the idea of capillary anisoperfusion and proposes the name "anisospastic retinitis." Koyanagi presented excellent microphotographs of the lesions seen in "albuminuric retinitis," some of which showed marked lesions of the arterioles, which, however, he thinks, are due to invasion of the arteriolar walls by phagocytic pigment-epithelial cells. It is noteworthy, however, that the vascular lesions he demonstrated compare very closely with those found in the arterioles of muscles and of the kidneys.

Lobeck, of Jena, and Thiel, of Frankfurt, reported on a series of measurements of the diameters of the retinal vessels in various types and phases of hypertensive disease. For these measurements, they used a new type of instrument which should be superior to the previous graticule methods and should give us a more accurate idea of what actually happens to the lumen of the vessels in hypertension.

A number of papers were presented on the use and value of measurements of the retinal arterial pressure with the dynamometer of Bailliart. This instrument seems to be more systematically used in Europe than in America and is said to yield significant results in investigations of suspected cerebral lesions and in lesions of the optic nerve and retina, whether associated or not with an elevation of systemic blood pressure. A paper that deserves further study along these lines was presented by Espildora-Luque, of Santi-

ago, Chile, on "Solitary retinal arterial hypertension."

The symposium on endocrinology brought out the fact that there is still much uncertainty as to the influence of specific endocrine insufficiencies on specific eye diseases. The difficulty inherent in endocrine studies was well brought out in the excellent summary of the various endocrine syndromes presented by Snapper, of Amsterdam. Professor Snapper emphasized the close interrelationship between the different endocrine glands and the difficulty of determining at times which of the glands is involved primarily. A paper of considerable interest was presented by Blatt, Bratianu, and their co-workers of Bucharest. They demonstrated roentgenographic changes in the sella in 28 of 37 cases of cataract and evidences of reduced pituitary function in all. Wibaut, of Amsterdam, reported good results from the treatment of retinitis pigmentosa with memformon (theelin).

Two days of the Congress were devoted to sessions of the International Organization against Trachoma and of the International Society against Blindness. The etiology of trachoma came up again for discussion. Thygeson, of New York, reported on his studies of the Halberstaedter-Prowazek elementary bodies which he believes to be the morphologic unit of trachoma virus. Apparently, trachoma is considered now to be most probably a virus rather than a bacterial disease. Busacca, of São Paulo, Brazil, and Cuénod and Nataf, of Tunis, reported the findings of infraorganisms of the rickettsia family in cases of trachoma. The campaign against trachoma and purulent ophthalmia in Egypt is apparently well organized, and very excellent work is being done by the Egyptian ophthalmologists in the treatment of these diseases in spite of the tremendous number of cases which must be handled.

PECULIAR PUPILLARY REACTION TO COLD STIMULATION IN HORNER'S SYNDROME

DR. A. G. ATHENS, Duluth, reported the following case not only because of the unusual nature of its distinguishing symptom but also with the hope that, with careful study in the attempt to correlate the findings with our present knowledge of the underlying anatomy and physiology, it might be the means of throwing a little light on a somewhat confused subject.

A young medical student, aged 20 years, home on vacation, consulted him on December 20, 1937, because he had noticed for four weeks previously that, when he took a drink of cold water, the left pupil would dilate irregularly. On questioning he stated that the same thing occurred but to a less degree when he washed his face or took a bath in cold water. The right pupil was not so affected.

This patient had been treated by him in August and September, 1937, for a superficial marginal corneal ulcer of the left eye. This was treated with local applications, on two occasions, of 5-percent mercurochrome, and atropine, 0.5 percent combined with 1:6,000-mercurybichloride ointment for a period of about three weeks. The pupil was back to normal size at the beginning of school on September 28th. There was no evidence of iritis, and the pupils were equal in size and reacted normally to light and convergence. The media were clear and the fundi negative. One month previous to the onset of the ulcer an abscessed tooth had been removed. Two years previously he had been treated for a similar corneal ulcer by another oculist. He was then under observation for one week. The oculist reports that he saw nothing otherwise abnormal about the eyes. Since that time the eye had been slightly injected at times.

At the age of 13 years, in 1930, he was taken to his family physician because of

obesity. His weight had been increasing abnormally for two or three years previously. He was somewhat listless, apathetic, and dull in school. Examination showed him to be 50 pounds overweight, to have a female distribution of the pubic hair, and underdeveloped genitalia. Basal metabolism was -9 . A diagnosis of Froehlich's syndrome was made and the patient was treated with antuitrin and thyroid extract. After a few weeks there were definite signs of improvement, and the development thereafter appeared to progress along fairly normal lines.

On July 7, 1937, he was admitted to a hospital for study of a lymphadenopathy. It had been noted that various groups of lymph nodes had been enlarging over a period of five months. Examination revealed cervical, axillary, epitrochlear, and inguinal nodes greatly enlarged but not tender. Two nodes from the left cervical group were removed for examination. One of these proved to be caseous. Though a definite diagnosis of tuberculosis could not be made, this was strongly suspected, since the patient had had considerable contact with a maternal grandmother and two aunts who had had this disease. All serological and agglutination tests were negative. X-ray films of the chest were negative. Pulse and respiration were normal throughout his three weeks' stay in the hospital. X-ray therapy was used on the enlarged nodes.

Examination on December 20, 1937, revealed a rather tall, though normally developed, well-nourished young man, apparently a little worried about his condition. He was much interested in the examination and was very cooperative. He was of a rather emotional nature. Several moderately enlarged, fairly discrete, insensitive nodes were found in the neck below the mandibular angles on both sides. A distinct, firm mass measuring 3 by 2 by .5 cm. occupied the region of the left

parotid gland. A similar but much smaller, bean-sized mass was felt in the corresponding position on the right side. These were freely movable under the skin and overlying structures, and were not tender. There was a small surgical scar one inch below the left ear.

The pupil of the right eye in ordinary light measured 4.5 mm. and reacted normally to light stimulus, convergence, and consensually. The upper lid drooped slightly, but the levator functioned normally. There was no enophthalmos. The pupil of the left eye was round and measured 2.5 mm. It contracted promptly and regularly to light and promptly returned to its original size. It also reacted promptly to convergence and consensually. In a semidarkened room it dilated regularly to 7 mm. while its fellow pupil dilated to 8 mm. A 4-percent solution of cocaine dilated the right pupil to 9 mm. and the left to 3.5 mm. Epinephrine hydrochloride 1:1,000 solution dropped into the left conjunctival sac, repeatedly, had no effect on the pupil. One drop of 1-percent homatropine hydrochloride dilated the left pupil and the greatest dilatation was medialward. About six weeks later a small drop of epinephrine injected beneath the conjunctiva of the left eye dilated the pupil quite widely.

When the patient took a swallow of cold water the pupil of the left eye dilated markedly, downward and inward, giving it a distinct pear shape. This followed immediately on taking the water and the pupil promptly returned to its former size and shape—the entire procedure occupying three or four seconds. The reaction resembled an ameboid movement. During the reaction the patient observed a "peculiar sensation" as though the vision dimmed slightly. Washing the face or dipping the hands into cold water produced the peculiar dilatation of the pupil but to a less degree. Warm water either

swallowed or on the hands or face did not affect the size or shape of the pupil. When pressure was made on the left anterior faucial pillar the reaction occurred but not so markedly as with cold water in the mouth. Considerable pressure over the cervical nodes and along the carotid sheath produced no effect on the pupil. Seven weeks after this phenomenon was first noted by the patient it suddenly could no longer be elicited.

The cornea of the left eye showed only a very faint marginal opacity at the site of the former ulcer. The corneal reflex was present. The iris showed no evidence of atrophy and was uniformly colored to match that of the right eye. The other media were clear throughout. The retinal vessels showed no increase in caliber in comparison with those of the right eye. Both fundi were otherwise normal. The tension was normal and no appreciable difference in accommodation between the two eyes could be determined. The visual fields were normal for form and colors. The extraocular muscles were in balance. Visual acuity measured 20/15 in each eye.

This patient presented an atypical picture of Horner's syndrome with the added bizarre pupillary dilatation on peripheral cold stimulation. The signs commonly described as characterizing Horner's syndrome are (1) miosis, (2) narrowing of the fissure from drooping of the upper lid, (3) enophthalmos, (4) unilateral absence of sweating, and (5) hemiatrophy of the face. To these physiologists have added (6) failure of the pupil to dilate with cocaine, (7) dilatation of the pupil with epinephrine in the conjunctival sac. This case differs, then, from the classical Horner's syndrome in the following details. Enophthalmos was not present. As this is by no means a constant or even a common finding in sympathetic paralysis it will not be further considered. Opportunity was not given at the first examina-

tion to study the effects of sweating. The pupil dilated slightly but definitely with cocaine. It did not dilate with epinephrine in the conjunctival sac. Peripheral cold stimulation caused, for a period of six weeks, a dilatation of the lower nasal portion of the pupil.

A fairly careful search of the literature has revealed few similar cases and no such reaction to cold stimulation. Carline observed transitory dilatation of one pupil which remained so for several hours or days. He concluded that the patient was hysterical. Wiesner reported the case of a woman, 60 years old, who had paralysis agitans and also typical Horner's syndrome, and whose pupils were "cat-like and dilated when she took a sharp breath." Erlenmeyer observed bizarre behavior of the pupils of a hysterical woman of 47 years. They continued to change from oval to round, dumb-bell shape, and even assumed ameboidlike movements. Coppez recorded the case of a girl who had mydriasis of one eye which changed to miosis when her head was bent forward. The miosis was accompanied by severe pain. The patient had mediastinal adenitis and Coppez believed that inclining the head caused the enlarged glands to press on the cervical sympathetic producing the pupillary change. Rosenfelt reported a case of carcinoma of the esophagus involving the cervical sympathetic trunk. Typical Horner's syndrome was present, and the pupil dilated markedly when pressure was made over the area. Ehlers reported a case of hippus associated with Horner's syndrome in acute anterior poliomyelitis. Cases of essential iris atrophy, with the pupil assuming, at different times, many shapes have been recorded by Harms, Casey Wood, deSchweinitz, Lane, Zentmayer, and McKeown. In all these cases the lesions were unilateral. While the pupil in this condition dilates irregularly, the ir-

regularity is due to contractures and distortions of the remaining live tissue. These cases, when followed, terminate in glaucoma. Schur studied 34 cases of cervical-sympathetic paralysis and found that psychic stimuli caused dilatation of the pupil on the affected side in all.

Any attempt to explain the atypical features in his case—namely, the behavior with cocaine, epinephrine, and cold stimulus—will naturally involve a review of the anatomy and physiology of the sympathetic control of the pupil. Unfortunately, this is not thoroughly understood and there is controversy on a number of points. Physiologists and neuro-surgeons have found that removal of the superior-cervical ganglion does not always abolish the sympathetics in the eye nor even those to the dilator muscle. They have found it necessary to remove, in addition, the superior-thoracic ganglion from which fibers may follow the vertebral artery, to end, according to Duke-Elder, in the ciliary ganglion, or to remove the ciliary ganglion itself.

DeTakats and Clifford, reporting the results of sympathectomy for retinitis pigmentosa in six patients, stated that in two of these, in which the operation consisted in removal of the superior-cervical ganglion, Horner's syndrome did not develop, and in one case an incomplete Horner's syndrome developed. The test used for complete denervation was failure of cocaine to dilate the contracted pupil. Schur found that cocaine caused a slight dilatation of the pupil in all his 34 cases. This, he thought, was due to relaxation of the sphincter. This view was first expressed by Kuroda in 1915 and differs from that of Duke-Elder, Adler, and others who accept the view that cocaine acts by exciting the sympathetic. Duke-Elder states that although the reaction to cocaine is present immediately after section of the postganglionic fibers

it disappears after degeneration of the nerve.

The slight dilatation to cocaine, then, in his case can probably be accounted for on this basis and is not inconsistent with what can be expected in Horner's syndrome in an early stage. We should expect, however, this reaction to disappear soon.

We may now consider the failure of epinephrine to dilate the pupil in this patient. Epinephrine in 1:1,000 solution when dropped into the conjunctival sac does not dilate the pupil in the normal eye. When epinephrine is injected subconjunctivally or when the epinephrine content of the blood is suddenly increased the normal pupil will dilate. When the superior-cervical ganglion is removed the pupil is still more responsive to epinephrine, even when it is dropped into the conjunctival sac. Physiologists have long known that smooth muscle deprived of its nerve supply becomes hyperirritable to epinephrine. This appears to be a property peculiar to unstriated muscle supplied by sympathetic nerves. In such experiments on the eye the pupil is spoken of as "sensitized"—the "paradoxical pupil" of Langendorff. This sensitization appears to diminish with time although it is not completely abolished even after degeneration of the nerve fibers. Hartman and Loder and Itikawa found the effects of epinephrine upon the denervated pupil to be more striking when their experiments were performed within a few days after removal of the cervical ganglion. One would then expect epinephrine response, as cocaine response, to diminish after the nerve fibers had had time to degenerate. Unfortunately, in reports of clinical cases the time element, in regard to the effect of these stimuli, has been given very little consideration.

Arnold Knapp called attention to the effect of epinephrine on the glaucomatous

eye, where it dilates the pupil even before clinical signs of the disease have appeared. This has been accepted as a valuable diagnostic sign in early glaucoma and probably indicates a hyperirritability of the dilator mechanism.

Hubert recently reported several cases of Horner's syndrome to support his contention that it is necessary, in order to sensitize the pupil, that the lesion involve the superior-cervical ganglion or the post-ganglionic fibers. If the lesion, he contends, is in the cord or the preganglionic fibers the dilator muscle retains its connection with live nerve cells and will not be rendered hyperirritable to epinephrine. He advocates the use of epinephrine to localize lesions involving the sympathetic pathway. Byrne has shown, however, that lesions in the cord or brain stem also render the pupil hyperirritable to epinephrine, excitement, and so forth. Certain systemic diseases such as diabetes and exophthalmic goiter may render the pupil hyperirritable. A weak solution of cocaine previously instilled into the eye appears to sensitize the pupil to epinephrine. This may, at times, account for the erroneous impression that epinephrine dilates the normal pupil.

It is difficult to correlate in this case the reaction to cocaine and the absence of a reaction to epinephrine. It is suggested, as a speculation, that cocaine was more completely absorbed from the conjunctiva than epinephrine and that, had the patient been seen earlier, when the muscle was perhaps more irritable, a reaction to epinephrine would have occurred.

Why did the pupil dilate only on one side? It is possible that, due to a difference in development or a slight atrophy on the temporal side, this portion lost its irritability sooner than that which reacted. Another possible explanation may be found in the peculiar enervation of the dilator muscle. Braunstein showed that

by stimulating the temporal long ciliary nerve, dilatation of the outer upper half of the pupil is produced, and after severing the temporal nerve and stimulating the cervical sympathetic, dilatation of the inner lower half of the pupil occurs. It is possible to believe that the fibers of these two nerves were so separated in the cervical chain or plexuses that those composing the nasal nerve were the ones that escaped, for a time, the destructive lesion. Indeed there is considerable experimental evidence that the pupillodilator and vasomotor fibers run from the ciliospinal center in separate paths.

The patient was reexamined on February 11, 1938. There was a definite hemiatrophy of the left side of the face, and this side remained dry while the right side perspired. There appeared to be a definite enophthalmos even after the drooping lid was lifted. However, none was found with the exophthalmometer, and the appearance of enophthalmos could doubtless be attributed to hemiatrophy of the face. Cocaine no longer dilated the pupil, neither did the pupil dilate spontaneously in the dark. It was therefore reasoned that the reaction of the sensitized pupil to cocaine and in the dark is of a transitory nature.

Discussion. Dr. Henry P. Wagener said studies related to the sympathetic nerve supply to the eye are always of considerable interest. The exact origin of these nerves and their mode of action have not been fully determined as yet. As Dr. Athens has pointed out, a complete Horner's syndrome is not produced in most cases by a simple removal of the cervical-sympathetic ganglia. If the anterior roots of the first and second thoracic ganglia are sectioned also, ptosis, miosis, and failure of the pupil to dilate with cocaine will result in most cases. Enophthalmos is not, however, an early effect of such an operation. If enophthal-

mos occurs at all, it would seem to be the late result of atrophy of the orbital tissues associated with the facial hemiatrophy.

The effect upon the general sympathetic system of local application of cold is also of considerable interest. It has been shown by Hines and Brown that immersion of the hand in ice water for one minute will cause an elevation of blood pressure that is greater in the hypertensive or prehypertensive individual than in the normal person. Hines and Brown thought that a widespread vasopressor reaction occurred through the mechanism of a neurogenic reflex arc. That the reaction was not due to increased secretion of adrenalin was shown by its occurrence in adrenalectomized dogs and in patients with Addison's disease. The reaction occurs also in patients around whose arm a tourniquet is placed to shut off the return flow of blood from the hand in the ice water.

The dilatation of the pupil which occurred in Dr. Athens's patient following the local application of cold at a distant point presents further evidence of a widespread stimulation of the sympathetic nervous system by cold applied to a relatively small area of the periphery. The dilatation of the pupil was not necessarily a response to an increased secretion of adrenalin.

ETIOLOGIC FACTORS IN MYOPIA

DR. T. R. FRITSCHÉ, New Ulm, Minnesota, stated that the causes of axial myopia have been the subject of considerable discussion and many varied and diverse explanations have been given. Various authors have advocated such theories as acquired disease of the posterior segment, uric-acid diathesis, gravity theory, endocrine imbalance, calcium deficiency, epinephrine deficiency, and focal infections as being causes of myopia. Some have denied the influence of heredity, some believe it to be due to lues

or tuberculosis in the parents, some believe that measles plays an important role, some stress the importance of acquired lues, while others believe that it only augments an already existing myopia. The mechanical theory has many advocates, who believe that the oblique muscles and the rectus muscles in their action compress the globe and cause it to bulge posteriorly at the same time that the optic nerve exerts a pull on the posterior globe during convergence. There are those who believe that myopia may be due to a tendency to undue expansion or delay in the toughening process of the sclerotic. Others believe that it may be due to excessive near work or strain, if either eye has had some slight injury. The theory has been advanced that a deficiency of adrenocortical substance may result in an increased formation of aqueous humor which will lead to glaucoma if the eyeball is strong, or to myopia if the sclerotic coat is weak. The observation has been made that it does not occur among the savage races and that it is most prevalent in those who do prolonged close work during the growth period.

Statistics taken by Schleich on 300 infants eyes showed all to be hyperopic. A summary of the examination of 2,400 eyes of small children in Germany showed only nine to have myopia. Stocker in Lucerne examined 4,614 eyes of children between the ages of 7 and 16 years, without cycloplegics, and found 8.4 percent to be myopic. Callan found an incidence of 1.2 percent myopia in Negro children in grade schools and an incidence of 3.4 percent in high schools, out of a total of 457 children who were examined. A statistical study in the United States showed no myopia under 5 years of age, an incidence of 8.1 percent between the ages of 5 and 10, and an incidence of 25.7 percent between the ages of 10 and 20.

Children's eyes are normally hyperopic

and this hyperopia decreases as maturity is reached, due to the growth of the eyeball. It is only natural that there are normal variations in the size of the eyeball, some of which may even be large enough to result in moderate degrees of myopia; yet a myopia of this type should not be considered pathological or due to any of the numerous causes given above. Likewise there are many cases in which the larger size of the eyeball may be purely hereditary and as such the myopia cannot be considered as being due to any of the various causes. Those eyes should be considered as pathologically myopic, in which the myopia appears or progresses at a rate faster than the normal growth rate of the eye.

In the following series of cases the majority had a considerable degree of myopia ranging from 1 to 10 diopters; two cases are included in which there was mixed astigmatism and in which the minus meridian exceeded the plus meridian. During the year 1934 there were 35 cases of congenital lues on record at Ancker Hospital. Several of them were in infants and consequently were not tested. Twenty-eight patients, in age between 3 and 20 years, were refracted under cycloplegia. Sixteen of the 28 (or 57 percent) were found to be myopic, the other 12 (or 43 percent) were found to be normal or hyperopic. Eight of the 35 (or 23 percent) of these patients with congenital lues had interstitial keratitis, and all eight in this particular group had a considerable degree of myopia. In one half of these cases of congenital lues with myopia there were somewhat similar errors of refraction in the two eyes. The others had a considerable difference, both in the degree of myopia as well as a decided difference in the axis of the astigmatism.

It is hard to say what influence treatment of the congenital lues has on the

course or incidence of the myopia. All of the cases at Ancker Hospital were under observation or treatment. There was a record of only one patient, aged 19 years, who had had a refraction test two years before, and his myopia was found to be increased by one-fourth and one-half diopter, respectively, in right and left eyes. Whether there would be a greater incidence of myopia among undiscovered and consequently untreated cases of congenital lues cannot be determined from this series of cases. Likewise it would be interesting to refract these patients again and observe their progress.

Two interesting cases were seen that were not in the Ancker series. These were a sister, aged 29 years, and a brother, aged 24 years. Both father and mother were hyperopic, and both were luetic at the time of the birth of the girl, who developed interstitial keratitis and malignant myopia, with the left eye much worse than the right. The boy, who was born after the parents had been under some treatment, did not develop interstitial keratitis. He has two diopters of simple myopic astigmatism at axis 180 degrees in each eye.

Because of the fact that there was a definitely increased incidence of myopia among congenital luetic patients, it was thought worth while to look for evidences of congenital lues among children and young adults afflicted with myopia. In addition to looking for the usual signs of congenital lues, such as Hutchinson teeth, chronic middle-ear deafness, interstitial keratitis, rhagades, saber shins, and fissures on palms and soles, peculiar formations of the cranium, and a routine Wassermann test, the eyes were inspected with a slitlamp for loss of pigment on the pupillary border, and luetin tests were made. The luetin test is a skin-sensitivity test for the *Spirochaeta pallida* that has

been discarded for many years in favor of the Wassermann and its modifications. The diagnosis of congenital lues in the absence of positive serology, definite clinical signs, or knowledge of active lues in the parents is practically impossible, and on this account it is thought that the luetin reaction might prove to be valuable. After examining 25 myopic patients and finding nothing more than a few having decreased or absent pigment of the pupillary margin and two questionably positive luetin reactions, he became discouraged and discontinued doing all the extra work on the routine refraction cases. These three were aged 29, 37, and 50 years. All three had negative Wassermann reactions and positive luetin tests. The parents of the two older cases were dead and there was nothing in the history to suggest lues. The younger patient had bilateral chronic otitis media. His mother was dead, but his father was living; a Wassermann test was negative, and the father likewise denied any luetic infection. Viewed with the slitlamp all three of these persons had interstitial keratitis typical of that seen in the interstitial keratitis of congenital luetics.

Just how the congenital syphilis acts to produce an increased incidence of myopia is a debatable question. Possibly there may be a low-grade luetic scleritis. At least in the cases of interstitial keratitis, in which one actually sees the disease of the cornea and which often results in the stretching or distortion of the cornea, one could readily imagine that this disease could exist in the sclera as well as in the cornea and result in an enlarged eyeball. Likewise a person afflicted with congenital lues can be assumed to be constitutionally inferior and naturally would be more apt to suffer some endocrine or nutritional disturbances which may act in some way to weaken the

sclerotic coat of the eyeball. In determining the size of a given eyeball, two factors must be considered. In the first place there is a hereditary factor. This factor determines a tendency toward a certain size of eyeball, as well as a tendency toward a certain degree of toughness of the sclerotic coat. The second factor is the intraocular pressure. Both the intraocular pressure as well as the toughness or tensile strength of the sclerotic coat may be altered by numerous conditions. The intraocular pressure may be altered by endocrine, vasomotor disease, physical or mechanical conditions. The toughness of the sclerotic coat may be altered by growth, disease, trauma, endocrine, and nutritional causes. Thus in the final analysis it can be seen that pathological myopia is not due to any one cause, but to a number of conditions working together, and that a condition which is most important in producing one case of myopia may be the least important in another.

SOME PRACTICAL CONSIDERATIONS IN THE INTERPRETATION OF VISUAL FIELDS

DR. HAROLD F. WHALMAN opened his discussion with the admonition to observe standard conditions when taking visual fields, emphasizing particularly the necessity for adequate and constant illumination. For this he preferred artificial light, which, of course, can easily be controlled. He pointed out the importance of the quantitative method of plotting the perimetric fields and indicated that his prefer-

ence for this purpose was the tangent screen and a series of test objects ranging from 1 mm. to 40 mm. in size. The patient should sit at a distance of two meters from the point of fixation.

Dr. Whalman then presented various characteristic field defects. He pointed out the difference between the neurasthenic and the hysteric fields. In neurasthenia the field is a spiral, starting out at approximately normal limits in the periphery and gradually decreasing in extent as each meridian is tested until the field has come in close to the point of fixation. In hysteria the concentrically contracted field for one test object shows no increase in extent when larger test objects are used.

In retrobulbar neuritis green may be lost entirely while the field for red is reduced considerably. The papillomacular bundle is frequently involved, giving a central or paracentral scotoma. Toxic amblyopia may be considered a chronic variety of retrobulbar neuritis with the involvement beginning in the ganglionic retinal cells and then spreading to the nerve fibers of the papillomacular bundle. This again produces paracentral scotoma. Bizarre fields are produced by chorio-retinitis. In primary optic atrophy there is an early and rapid loss of the red and green fields as well as the nasal form fields.

Dr. Whalman then outlined the possibilities of field changes in hypophyseal tumor, stating first that in some of these cases there is an early occurrence of paracentral scotoma due to a toxic effect on the papillomacular bundle. Later the effects of pressure or stretching of the chiasmal crossed fibers can be detected by the appearance of quadrant anopsia and hemianopsia. A field which starts as a bitemporal defect might later be changed into a homonymous defect by the bursting through of a pituitary stroma to one side of its confines, producing pressure on only

one optic tract. It is possible also for unilateral blindness to occur with a normal or partially changed field on the other side.

Discussion. Dr. Clifford Walker stated that 50 percent of pituitary tumors produce homonymous field defects rather than bitemporal, so that the latter cannot be considered typical of pituitary lesions without cognizance of the former.

A TREATMENT FOR CHRONIC DACRYOCYSTITIS

DR. PAUL SOUTHGATE read a paper on this subject which was published in this Journal (October, 1938).

DR. ALEXANDER G. FEWELL, *chairman*

THE ASSOCIATION OF AN ANNULAR PIGMENT BAND ON THE POSTERIOR CAPSULE OF THE LENS WITH A KRUKENBURG SPINDLE

DR. WILLIAM ZENTMAYER reported the case of a boy aged 16 years, who showed in each eye a characteristic Krukenberg spindle. On the surface of the posterior capsule of the lens of each eye there was an annular band of brown pigment. As seen with a +20 D. lens of the ophthalmoscope it had an average width of .5 mm. and was situated about 2 mm. in from the equator of the lens. The margins of the band were more or less serrated. In the right eye the circular band was broken at points corresponding to the 8- and 4-o'clock positions, the gaps being about 2 mm. wide. At these breaks short tags of pigment were seen directed toward the tips of the ciliary processes.

In the left eye the band was unbroken, but there were a few pigment lines running toward the equator of the lens. The refraction was a compound myopic astigmatism.

Cases from literature were cited in which Krukenberg spindles were seen to develop in eyes that were without inflammatory changes.

The anomaly on the posterior capsule of the lens is explained by Mann as being due to the maintenance of the contact between the tips of the ciliary processes and the lens for too long a period. The ciliary ring increases in diameter more rapidly than does the lens, with the result that the ciliary processes are withdrawn from the lens and a space is left between the two.

In view of the cases of Krukenberg spindle cited and the opinion expressed by several other writers as to the pathogenesis of this lesion, the author concludes that in the case reported it seems reasonable to believe that granules freed from the pigment line on the posterior capsule of the lens were carried by the circulation of the fluids of the eye into the anterior chamber, where the thermal currents deposited them on the posterior surface of the cornea.

Discussion. Dr. Alfred Cowan said that Krukenberg spindle is of much more frequency than it was considered to be before the advent of the corneal microscope. Very often the same type of pigmentation that is found in Krukenberg spindle can be seen with the slitlamp, but it would escape notice by the ordinary methods of examination with oblique illumination. The pigment is deposited all over the posterior surface of the cornea and the spindle formation is the result, merely, of a denser arrangement over the spindle-shaped area. While it may be that the pigment-ring imprint on the posterior surface of the lens is congenital in most in-

stances, he has seen this condition as the result of inflammation several times.

DELAYED REMOVAL OF MAGNETIC FOREIGN BODIES FROM THE VITREOUS

DR. CHARLES R. HEED detailed the history of three patients and emphasized the importance of accurate localization and early extraction of magnetic foreign bodies, before the advent of degenerative changes which, he believes, result in an overwhelming percentage of all cases where an ultraconservative policy has been pursued. He advocates a scleral incision when the metal is located behind the lens, and counsels against the introduction of any magnet tips into the vitreous.

Case D. B. was examined five days after the accident. Vision O.D. was 20/100. There was an incomplete coloboma at the 11-o'clock position, due to an operation by the company physician to remove particles of torn iris, on the day following the accident. A small wound of the cornea, iris, and lens periphery was found with a posterior star opacity. A magnet extraction was made through the scleral incision on March 11, 1937. Two months later the vision was 20/20, and the eye was quiet. Ophthalmoscopic and slitlamp examinations exhibited a less dense opacity of the posterior subcapsular star.

Case B. R. was examined June 23, 1937, 112 days after the accident. The pupil was dilated; the iris was copper colored, and pigment cells were seen on the anterior nasal quadrant posterior to equator. Diagnosis: retinochoroiditis with symptoms of siderosis. After localization, a metallic body, 1.5 mm. in size, was extracted by means of a magnet through the scleral incision. At the last visit, July 20, 1937, vision was 20/30. No deposits on the capsule were seen, and only a few vitreous opacities.

Case T. J. A. was examined six days after the injury. The patient was myopic, with corrected vision of O.D. 20/20, O.S. 20/200. A particle of metal from an iron pin or hammer had entered the left eye through the upper lid. The X ray located the metal in the vitreous. Vision became blurred in 48 hours and there was severe pain three days later. A delicate haze in the vitreous and a somewhat blurred disc were seen, but there was no apparent retinochoroidal lesion nor hemorrhage. The slitlamp showed marked wrinkling and folds of Descemet's membrane, many cells in the aqueous, no apparent change in the lens, and an increase of cells in the vitreous. Diagnosis: iridocyclitis. Localization demonstrated a metallic foreign body, spherical, 2 mm. in diameter, in close proximity to the ora serrata, 4 mm. to the nasal side of the median line. A magnet extraction through the scleral incision, on the nasal side of the superior rectus, about 8 mm. posterior to the limbus, was made. There was no prolapse of vitreous or pigment. Severe pain was experienced for two hours. The patient slept well and was free from pain on the following morning. He was discharged on November 8, 1937; when examination showed vision in the left eye, corrected, to be 20/50. By means of the slitlamp, a few fine vitreous opacities were observed, but no hemorrhage nor visible retinochoroidal lesions. Descemet's membrane was clear and free from wrinkles, the capsule and lens were clear, and there were no cells in the aqueous. A report from his physician made two months later, gave vision, corrected, as 20/20.

Discussion. Dr. H. Maxwell Langdon reported on a patient, whom he had seen about twelve years ago. She had been to one of the large hospital clinics after having had a needle strike the eye from a machine on which she had been sewing. She herself suggested an X-ray examination,

but was told there was no foreign body in her eye. Not satisfied with this, she went to a private physician, who also assured her that an X-ray examination was unnecessary. By this time, her employer had notified the insurance company. The X ray showed a part of the needle, over one-half inch long. It had been in the eye almost a week when he saw her. Fortunately, a magnet attracted the end of the needle and it came out through the posterior scleral wound readily. The result was an eye with a vision of 5/9.

Another case which had always interested him was that of an employee of the Pennsylvania Railroad in its shops at Olean, New York. This man felt something strike his eye while at work and very promptly an X-ray film was taken, which was said to be negative. The eye was free from inflammation, the vision was normal, and he was told that there was no foreign body in his eye. In a short time he returned saying that he had no pain and could see; but he was sure there was something in his eye and the same procedure was gone through again with negative findings. He returned again after an interval of time but was sent to Philadelphia. Dr. Newcomet localized a very small foreign body, not as large as the head of a pin, which was easily removed with a magnet, and the patient returned to work, there never having been any inflammation of the eye and the vision never having been less than 6/6.

Unless the foreign body is in the anterior chamber, Dr. Langdon favors removal by the posterior route.

Dr. Leighton F. Appleman agreed with Dr. Heed that foreign bodies should be removed as soon as possible after their presence within the eye has been established. It is not always possible to see a foreign body within the eye, due to hemorrhage; therefore X-ray examination should always be made. The amount

of intraocular disturbance may vary considerably, depending upon the position of the wound of entrance and the size and shape of the penetrating particle. Also the subsequent reaction will depend upon whether infection has been introduced with the foreign body. Clean, magnetic bodies can often be removed through the wound of entrance; if this is not possible, an incision through the sclera may allow of its passage after the tip of the magnet is presented at the opening.

Dr. Walter I. Lillie said that he had removed an intraocular foreign body situated in the vitreous of the right eye of a young man. It had entered the vitreous through the lower nasal sclera, just posterior to the ciliary body. His convalescence was uneventful, and the eye is now normal, except for a small area of healed choroiditis at the site of entrance and exit of the foreign body. His vision of 3/60 can be improved only to 6/60 with a +.50 D. sph. \approx +1.00 D. cyl. ax. 90°. The visual-field examination was quite interesting, inasmuch as he would only see the 10-mm. test object in the extreme opposite field from any avenue of approach. This, of course, does not conform with any type of organic field change, or that associated with amblyopia ex anopsia, or hysteria. Dr. Lillie is sure that the patient is malingering, and such a situation should always be thought of in a compensation case.

THE LATE RESULTS FROM CERVICAL SYMPATHETIC RESECTION IN RETINITIS PIGMENTOSA

Dr. E. B. SPAETH reviewed the results of seven cases and said that while no definite statement can or could be made, there are some indications present which seem to suggest that this form of therapy may be seriously considered in certain cases.

Discussion. Dr. William Zentmayer

said that if the pathology of pigmentary degeneration of the retina is what we believe it to be and the disease is an abiotrophy, he would not expect more than a transient improvement in the vision from a sympathectomy.

Dr. ROY MASON, *president*

METASTATIC ACTINOMYCOTIC CHOROIDITIS

Dr. JULE ELZ read a paper on this subject which will be published in this Journal.

Discussion. Dr. Harvey D. Lamb said that Dr. Elz is very fortunate in getting such an unusual specimen. For that matter, any eye with a metastatic or endogenous inflammation, that can be examined anatomically in the florid stage, is valuable. Dr. Elz's case with this organism is the only one of its kind ever to have been reported. Axenfeld in 1894 stated that in cases of metastatic septic endophthalmitis, if the involvement was bilateral, the primary change was usually in the retina. If only one eye was affected, the choroid, as a rule, was the first coat of the eye to be inflamed. Axenfeld, however, could give no explanation why in one individual the retina and in another the choroid should be the primary seat of the septic process in the eye. The septic emboli in the retina are very readily discharged from the retinal blood vessels into the vitreous. From the vitreous, the irritant coming in contact with the ciliary body and retina causes the formation of pus cells from these coats. As a consequence, the vitreous receives many pus cells and the eye is hopelessly lost. Dr. Elz demonstrated that in his case there was a primary deposit of the organism

in the choroid. He early noted clinically a complete detachment of the retina. The pus cells are all subretinal because they come from the infected choroid. In addition the choroid is generally densely infiltrated with pus cells. A panophthalmitis can occur from septic involvement of the retina or from a septic choroiditis.

INDIRECT CHOROIDAL TEARS

DR. LESLIE C. DREWES read a paper on this subject which will be published in this Journal.

Discussion. Dr. Harvey D. Lamb said that Dr. Drewes has shown how important it is, in a rupture of the choroid, to take a field of vision. Certainly, in one case that he saw very early, with hemorrhages that covered the retinal blood vessels, there must have occurred a tearing of the retinal tissues. It is novel to have a rupture of the choroid, without a tearing of the lamina vitrea, as Hagedoorn found anatomically. If there exists a simple separation of the pigmented epithelium of the retina, it is no choroidal rupture. The main trouble is that we do not have enough anatomical examinations of eyes with so-called choroidal ruptures.

Dr. B. Y. Alvis said the point was made that the yellow-pink portion of this tear resembled the lesion of the retina. That being the case it would seem that it should have destroyed the maculopapular bundle and have cut down the central vision very materially. The central part of the field should have been lost. It is more likely to be a lesion of the superficial portion of the choroid; whereas the white portion involves the entire choroid and the retina.

Dr. Drewes said the fact that this optic-nerve atrophy was noticeable in a week after the injury indicates the damage of the nerve fibers. Quite a number of such cases have been reported in the literature and about 20 cases of incomplete nasal scleral tear.

NONOPERATIVE IMPROVEMENT OF DIVERGENT STRABISMUS

DR. VINCENT L. JONES stated that an improvement in exotropia without operation is not unusual. The two cases here presented, being of 40 and 50 degrees divergence, are considered sufficiently unusual to warrant reporting them.

The first, a boy, 19 years of age, had a 40-degree divergence. Vision in the right eye was 20/24 and with -0.75 D. cyl. ax. 180° equalled 20/16. Vision in the left eye was 20/32, and with -0.50 D. cyl. ax. 180° equalled 20/16. A recession of the external rectus of the right eye was performed in October, 1936, and orthoptic exercises were instituted shortly thereafter.

In February, 1937, the patient's eyes were straight when fixating near objects, but the right eye diverged slightly when fixating distant objects. A second operation was advised, which the patient refused. However, orthoptic exercises were continued until the present, and now he is wearing comfortably a moderate over-correction for the compound nearsighted astigmatism. His eyes are straight when fixating distant and near objects, no suppression of either eye is observed, and the fusion is good.

The second case is that of a 35-year-old woman who had an alternating divergent squint for years. When first examined the divergence was 50 degrees, and there was no fusion. Vision in each eye was 20/30, and with -0.50 D. sphere equalled 20/20. Operation was advised but she refused, so an effort to determine if any improvement could be accomplished by exercises was made and continued to date with more or less regularity. Her eyes are now straight, and her fusion is good; she can read comfortably with four prism diopters, base out, before each eye.

These two cases, and particularly the second one, demonstrate very clearly

what a surprising improvement can be obtained in many cases by rather simple orthoptic exercises.

Discussion. Dr. M. L. Greene said he was interested in these cases because he very often saw such conditions when examining patients for the service. There was one case of a young man who had a definite tendency to divergence at times. He could not be measured for adduction, for as soon as prisms were in place, the eyes would diverge. He was overcorrected and in three or four months took another examination and passed the eye test.

Dr. B. Y. Alvis said that following Dr. Greene's suggestion in a paper presented

here some time ago, he tried overcorrection on a child 12 or 13 years old who had a divergence with a tendency to diplopia and who was not able to do at all well in school. The overcorrection was about 1.50 diopters with a good result, and the patient developed a very satisfactory degree of stereopsis. The thing that is puzzling in these periodic divergent cases is that a person may have a perfectly good stereopsis and still at times get an external deviation without diplopia, while at other times the eyes will be parallel and show good muscle function.

Directors: EDWARD JACKSON, President, LAWRENCE T. POST, Vice-President, DR. F. E. WOODRUFF, Secretary and Treasurer, WILLIAM L. BENEDICT, WILLIAM H. CRISP, HARRY S. GRADLE.

Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to Dr. Lawrence T. Post, 640 S. Kingshighway, Saint Louis.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver.*

Subscriptions, applications for single copies, notices of change of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 640 S. Kingshighway, Saint Louis. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Alnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

The New Year witnesses the Journal's embarkation on its twenty-second year. Due to the loyal support of the profession it is now possible to publish a bigger and better journal than ever before. The increase of paid subscriptions by more than 200 in the past two years has permitted the continuance of the larger issues introduced in January, 1937. If one may judge from the material now on hand awaiting publication the coming volume promises to be one of the best. The editors take this opportunity to thank the many contributors of original articles, and the abstractors who have devoted so much time for the benefit of others to reading, in many cases translating, and digesting the literature, to present it in condensed form for our readers. It is frequently hard work and always time consuming. To them go the most sincere thanks of the

editor and for them he wishes an especially happy New Year.

This year as heretofore an effort will be continued to present material of practical value to the ophthalmologist so that in each issue there will be much that the clinician can use in his daily work.

Letters were sent out in December to nonsubscribers, suggesting that the Journal would make a welcome gift to a friend or an ideal present for a family to give the ophthalmologist husband or father. This is a thought that we would like to convey to our subscribers, too. If you can help enlarge the subscription list you will do a service to the entire profession as well as to yourself, for new subscriptions permit the publication of a better magazine.

The past year, which marked the initiation of the third decade of the publica-

tion of the combined ophthalmic journals now known as the American Journal of Ophthalmology, furnished an occasion for a very enjoyable luncheon of the editors, collaborators, and stockholders, at the meeting of the American Medical Association in San Francisco. A similar subscriber's luncheon in Saint Louis this spring is being planned. It is hoped that there will be a large attendance.

Nineteen thirty-eight may not have been the best of years for business and profession, and we may not like the socialistic trend in medicine, but as we look the world over we can find a great deal for which to be grateful. So here's for a prosperous and happy New Year.

Lawrence T. Post.

SCIENCE AGAINST DICTATORSHIP

Scientific discoveries of facts or general laws are made by independent thinkers who test new ideas by their knowledge and experience and then submit them to the judgment of others best qualified to appreciate them. The progress of the world has depended on the free thought of great men. Shall it now be stopped to increase or sustain the power of dictators? Science, the growing knowledge of truth, now meets the challenge of dictatorship. Helpful guidance may be needed by children, but a time comes when each must choose, direct, and live his own life. Military power and political authority must not limit nor dictate to science.

Science has now gained a position in human service and direction equal to the influence formally exerted by custom, tradition, or statute law. Scientific truth is more powerful than any ruler. From the days of Vesalius and Harvey medical science has advanced more than under 1500 years of the dictatorship of Galen. The advance of science comes by the great

thoughts of free men. Such thinkers break down the traditions of the past and are foes of tyranny. Dictators cannot tolerate them.

Ophthalmology has contributed to, and shared in, the advances of modern science. Can it continue to do so under dictatorship that burns all books written by Jews and exiles all whose thinking it cannot control? If Hitler had then ruled Germany would Helmholtz, a direct descendant of the pacifist William Penn, have been appointed to teach physiology in the Naval Medical School at Kiel and been permitted to invent the ophthalmoscope? If communists had continued to control Paris, would the devout Catholic, Louis Pasteur, have been allowed to save the silk industry of France, exterminate anthrax, and prevent rabies?

Freedom of independent thought, and to teach what is proved, are more important to scientists than grants of money for research, or laboratories, or professorships, or titles of nobility. Germany and Italy have shared in the development of modern ophthalmology. But they cannot continue to do so when they refuse to hear teachers utter new scientific truths. Already the literature that comes in German or Italian journals is less important than it was before teaching positions were placed under Nazi and Fascist control. France, Britain, and America now take the leadership in scientific investigation and study of ophthalmology. Holland, Belgium, Switzerland, Scandinavia, Finland, and, perhaps, the Soviet Union, must be looked to for really important contributions to future ophthalmic literature.

Edward Jackson.

AMERICAN BOARD OF OPHTHALMOLOGY CHANGE IN METHOD OF EXAMINATION

With steady increase in the number of

candidates presenting themselves for examination, one of the most important problems in the work of the American Board of Ophthalmology is as to the type of examination which will most satisfactorily determine whether or not the candidate is entitled to the Board's certificate.

The Board has kept before it consistently the principle that its investigation of professional qualifications must seek to discover whether the candidate may safely be entrusted with the care of important ocular disorders, including errors of refraction and those serious conditions which call for surgical intervention.

In the earlier years of the Board, it was found practicable to divide the examination into two parts, both occurring on the same day. The first part was an oral examination which was completed by lunchtime. The second part was a written examination, held in the afternoon.

With much larger numbers of candidates to deal with, the Board decided a few years ago to omit the written examination, and to depend (so far as examination was concerned) entirely upon oral tests. While much has been said in criticism of any form of examination as a criterion of educational qualifications and ability, examinations do furnish information which it is difficult to obtain by any other means. Certain defects are inherent in oral examinations, other defects may be attributed to a written examination. To some extent each form of examination is complementary to the other.

After careful deliberation, the Board has now decided to use a new plan for examination of candidates. A practical and oral examination will be held, as before, at the time of meeting of the American Academy of Ophthalmology and Otolaryngology and of the American Medical Association, and also occasionally in relation to other important medical assemblies.

Sixty days prior to the date of the practical and oral examination, written examinations will be held simultaneously in various cities throughout the United States. The subjects covered in the written examination will include all the subjects previously covered by the Board's oral examination. It is intended that the first written examination shall be held on Wednesday, March 15, 1939, and candidates will of course receive due notice as to the places of examination.

Each candidate must take the written examination and must pass it satisfactorily before he may appear for the practical and oral examination. (He must also have presented acceptable case reports before appearing for the final examination.)

The oral examination to be held in Saint Louis on May 15, 1939 (at the time of the meeting of the American Medical Association in that city), will deal only with the following six practical subjects: External diseases, Ophthalmoscopy, Pathology, Refraction, Motility, and Practical surgery.

The Board announces that all applications for the written examination which is to be held on March fifteenth must be on file at the Board's office, 6830 Waterman Avenue, Saint Louis, not later than February 15, 1939. All correspondence on the subject must be addressed to that office.

Candidates whose applications are already in the hands of the Board will receive direct notification in regard to the new arrangements.

W. H. Crisp.

BOOK NOTICES

THE PRINCIPLES AND PRACTICE OF PERIMETRY. By Luther C. Peter, M.D. Fourth edition, cloth-bound, 332 pages, 222 engravings, and 5 colored plates. Philadelphia, Lea & Febiger, 1938. Price \$4.50.

This fourth edition of probably the best known book on perimetry by an American author is rather similar to the preceding editions. It is therefore apparently published because of the exhaustion of previous editions rather than for the presentation of new material in perimetry that has been brought out in the last few years. However, even small additions are valuable, as it is always of advantage to keep textbooks strictly up to date.

The subject of perimetry is obviously of very great importance. It is surprising how few of the candidates for the American Board of Ophthalmology are well prepared in this subject, although undoubtedly they do better now than formerly.

For some reason they have seemed to think that this subject is very simple and that a vague idea of general principles is all that is necessary.

Peter's book presents the subject logically and clearly. It is very readable and covers the field adequately. The first chapters are devoted to anatomy, physiology, and technique; the central division to general pathology of the visual field; and the latter part to the special pathology of the fields and various functional nervous diseases. The illustrations are good, being clear and easily understandable. It is a valuable book for the student of eye diseases and for the practicing ophthalmologist.

Lawrence T. Post.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is only mentioned in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision. | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Gallino, Juan. Rubeosis iridica. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 311-313.

The author reports a case of rubeosis of the iris in one eye of a diabetic patient 65 years of age. Some cases reported in the literature are mentioned. The author believes the condition to be produced by proliferation of blood vessels in the course of a torpid iritis.

Ramon Castroviejo.

Meyer, G. P. Uveal tuberculosis. *Jour. Med. Soc. New Jersey*, 1938, v. 35, March, p. 138.

Meyer discusses the diagnosis and treatment of uveal tuberculosis and states that specific desensitization is the most important curative measure.

Theodore M. Shapira.

Miklos, Andor. The late prognosis of operated cases of iridocyclitis. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 403-412.

Of twenty eyes with chronic iridocyclitis, repeated paracentesis or therapeutic iridectomy failed to improve and

even made conditions worse in thirteen eyes. Six of the eyes with favorable results had an iridocyclitis of rheumatic origin. Among six eyes with chronic iridocyclitis, cataract extraction was performed in five eyes, with failure by the extracapsular method and success intracapsularly in only one eye, in which the cyclitis had been stationary for years. Beside these cases, the author's material included forty eyes on which similar operations had been performed with analogous results. Iridectomy should therefore be performed in tuberculous iridocyclitis only when a secondary glaucoma cannot be relieved by conservative measures.

H. D. Lamb.

Mohamed, I. A. Studies of a series of cases of sympathetic ophthalmia. *Bull. Ophth., Soc. Egypt*, 1936, v. 29, p. 168.

A study of 27 cases of sympathetic ophthalmia is presented. Eight of the cases followed perforating or rupturing injuries, and ten occurred postoperatively, nine following iridectomy and one after cataract extraction. Nine cases were not related to trauma. The minimum time of development was eight

days and the maximum time four years. The histopathologic findings are summarized. Edna M. Reynolds.

Scardaccione, Mario. Urotropin in the therapy of sympathetic ophthalmia. *Boll. d'Ocul.*, 1938, v. 17, Feb., pp. 112-123.

Ten cases are reported. Six occurred after penetrating wounds of the eyeball and four after cataract operations. The age of the patients varied from 5 to 73 years, and the onset of sympathetic symptoms from twenty days to three months after the accident or operation. Urotropin was given by daily intravenous injection of 10 c.c. of a 40-percent solution. Better effects were obtained the sooner the treatment was started. In advanced and grave cases the effect was nil even in cases in which urotropin was used with other therapy. In four favorable cases the vision obtained was from 5/10 to 10/10, while in other cases the symptoms subsided with preservation of the sympathizing eye. (Bibliography.) Melchior Lombardo.

Van Lint. Sympathetic ophthalmia evolving during fourteen years. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 25.

The left eye was injured in 1924 and was enucleated thirteen days later, at which time the right eye had begun to show signs of cyclitis. This yielded to treatment but recurred in 1927, 1934, and again in 1936. Vision was reduced to one-third and treatment failed to improve it. One member in discussing the paper expressed the belief that the case might be one of tuberculous iridocyclitis lighted up by trauma.

J. B. Thomas.

Weekers, L., and Reginster, H. Contribution to the study of recurrent hypopyon iritis. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 31.

Dermatologists have recently called attention to a relapsing syndrome peculiar to women and characterized by thrush, acute ulceration of the vulva, and iritis. In some cases reported in men ulcers of the scrotum occurred in association with thrush and iritis. The authors report at length the case histories of two patients, one male and one female. The etiology is uncertain, but the evidence seems to indicate an infectious, allergic lesion. Blood transfusion has proved especially useful. It is noted that the ocular lesions include uveitis and not a simple iritis or even iridocyclitis. J. B. Thomas.

Yanes, T. R., and Ferrer, O. Spontaneous bilateral uveitis with dysacusia, alopecia, and poliosis. *Rev. Cubana de Oto-Neuro-Oft.*, 1938, v. 7, Jan.-Feb., p. 5.

The authors review in some detail the literature on the subject of uveitis associated with dysacusia, alopecia, and poliosis, and report two additional cases with complete clinical and laboratory findings. Edward P. Burch.

8

GLAUCOMA AND OCULAR TENSION

Allmaras, Fritz. Observations on a glaucoma family. *Zeit. f. Augenh.*, 1938, v. 95, Aug., p. 276.

The author gives a family tree in which eleven members of two generations had chronic simple glaucoma. Eight of the patients were women. He adds very brief notes on the eyes of the affected members. The four who were operated upon reacted well to trephining. This glaucoma form seems to be inherited directly and dominantly.

F. Herbert Haessler.

Barkan, Otto. Glaucoma: classification, causes, and surgical control. *Amer.*

Jour. Ophth., 1938, v. 21, Oct., pp. 1099-1114.

Bordeaux. The surgical treatment of glaucoma. Bull. Soc. Franç. d'Opht., 1937, v. 50, p. 142.

The author seeks amelioration and cure of glaucoma in its various forms by means of a modified Elliot technique. Under local anesthesia, a conjunctival flap is dissected down to the limbus, and the episcleral fascia is incised. With the galvanocautery, an opening is then made in the sclera, the point of contact of the cautery being 1 mm. from the insertion of the conjunctiva. By successive applications the hole is enlarged to 3 mm. The charred tissue is curetted away, a thin spatula is introduced, and the root of the iris and the angle of Schlemm are freed. The flap is replaced and sutured.

The author used the method sixty times, in all types of glaucoma. In 47 patients the tension was restored to a value of 25 mm. Hg (Schiötz) or less. In several cases a repetition of the operation was necessary to obtain the desired result. Clarence W. Rainey.

Fahmy, A. Y. Histopathology of a case of capsular glaucoma. Bull. Ophth. Soc. Egypt, 1936, v. 29, p. 164.

A case of glaucoma capsularis of Vogt in a patient of 75 years is described. There were capsular exfoliations of the lens, with fluffy felt-like tufts at the pupillary margin. No increase in tension was observed even under dilatation. Microscopic sections showed refractile granular masses on the posterior surface of the iris, with pigment granules and refractile masses adherent to the thickened anterior lens capsule. Edna M. Reynolds.

Fialho, Abreu, Jr. Spontaneous oscillations of ocular tension. Trabalhos

do Primeiro Cong. Brasileiro de Ophth., 1936, v. 1, pp. 315-324.

The author studied normal and glaucomatous eyes to determine the behavior of ocular tension throughout the day. The Schiötz tonometer was used. The nine patients presented normal eyes, and eyes with chronic simple, absolute, or secondary glaucoma. Fifteen conclusions are presented, the most important being as follows: Ocular tension varies during the day in both normal and glaucomatous eyes. As a rule, tension is higher in the morning than at night. Variations of tension are greater in glaucomatous than in normal eyes. In about 20 percent of normal eyes these variations do not occur. In only 8 percent of the eyes with chronic simple glaucoma were there no variations of tension during the day.

Ramon Castroviejo.

Mueller, Friedrich. As to insistence upon treating glaucoma without operation. Trabalhos do Primeiro Cong. Brasileiro de Ophth., 1936, v. 1, pp. 337-341.

The author discusses the different medical treatments reported in the literature for the care of glaucoma. The effect of irritation of the sympathetic upon ocular tension is also briefly discussed. Ramon Castroviejo.

Mueller, Friedrich. Glaucoma and pseudoglaucoma. Trabalhos do Primeiro Cong. Brasileiro de Ophth., 1936, v. 1, pp. 333-336.

The author discusses briefly some reports of Salzer and Thiel concerning glaucomatous symptoms in eyes without increase of ocular tension. According to the author, the term "pseudoglaucoma" or "glaucoma without increased tension" is incorrect. These are

really eyes in which instead of true glaucoma, there are other changes which simulate glaucomatous changes in the visual fields. Such field changes may be due to pressure upon the optic nerve by extraocular vessels or to degeneration of the optic nerve on account of circulatory disturbances.

Ramon Castroviejo.

Nemeth, Lajos. The constitution of glaucoma patients. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 222.

Fifty male patients with primary glaucoma from the eye clinics of Berlin and Budapest were followed up for several years with regard to types of constitution. Inflammatory glaucoma predominated in pyknotics, simplex in the asthenic type. In asthenics glaucoma sets in earlier, can be less influenced, and progresses more rapidly than in pyknotics. The blood pressure in asthenic glaucoma patients averages lower. Great climatic fluctuations render the therapy of a glaucomatous attack more difficult. In asthenics quieting of the nervous system, in pyknotics treatment of the vascular system is essential for preventing an acute attack.

C. Zimmermann.

Poos, F. Uveal vascular reactions and intraocular pressure. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 210.

Under conditions simulating inflammatory hypotony, the author attempted experimentally to increase and decrease locally the hydrostatic pressure of the blood in the capillaries. He also observed the behavior of intraocular tension. His results justify the assumption that the fluctuations of intraocular tension after toxic damage to the uveal terminal circulatory channels, and at first also in every acute inflammation,

are due to fluctuations of hydrostatic pressure in the capillaries.

C. Zimmermann.

CRYSTALLINE LENS

Berens, C., and Bogart, D. Immediate operative complications of cataract. *Rev. Cubana de Oto-Neuro-Oft.*, 1938, v. 7, Jan.-Feb., p. 27.

A brief analysis with respect to the immediate operative complications of 1,004 cataract extractions performed at the New York Eye and Ear Infirmary is presented, with recommendations as to their prevention.

Edward P. Burch.

Borley, W. E., and Tainter, M. L. Influence of dinitrophenol on the production of experimental cataracts by lactose. *Amer. Jour. Ophth.*, 1938, v. 21, Oct. pp. 1091-1098.

Bourne, M. C., Campbell, D. A., and Pyke, M. Cataract associated with an hereditary retinal lesion in rats. *Brit. Jour. Ophth.*, 1938, v. 22, Oct., pp. 608-613. (See Section 10, Retina and vitreous.)

Bueckler, M. Concerning the pathogenesis of zonular cataract. *Klin. Woch.*, 1938, v. 17, Sept. 17, p. 1325.

Two different groups must be distinguished. The pathogenesis of one is endogenous, of the other exogenous. An endogenous origin must be assumed for those zonular opacities which have their seat in the embryonic nucleus and are often hereditary. An exogenous genesis in connection with a constitutional pathologic condition must be assumed for the zonular cataracts, always bilateral, which are located in more or less extensive cortical zones around the embryonic nucleus and which therefore were developed post partum.

The etiologic factors which produce this latter group are largely unknown. The author could not confirm a regular association of this type of cataract with rickets or infantile tetany, two factors to which general opinion attributes it. For solution of this problem more exact classification and sharp separation of the various types are necessary.

Bertha A. Klien.

Bunge, E. The cholesterin content of normal and cataractous human lenses. *Graefe's Arch.*, 1938, v. 139, pt. 1, pp. 50-61.

Forty-four normal and fifteen intracapsularly extracted cataractous lenses were investigated as to their content of cholesterin. During life, the total amount of cholesterin in the normal human lens increases to about five times that in the new-born. Lenses with mature cataract show a normal absolute amount of cholesterin.

H. D. Lamb.

El-Atawi, M. A. Ectopia lentis. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 159.

A case of ectopia lentis is described in which the right lens was dislocated up and out and the left lens down and in. A brief discussion of the frequency of ectopia lentis, the position of displacement, its causes, clinical signs, and treatment is included.

Edna M. Reynolds.

Fahmy, A. Y. Elschnig-Török-Stanculeanu's intracapsular extraction. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 136.

The results of 160 cases of intracapsular cataract extraction are reported.

Edna M. Reynolds.

Finlay, C. E. Treatment of incipient cataract by means of vitamin C. *Rev.*

Cubana de Oto-Neuro-Oft., 1938, v. 7, March-April, p. 33.

The author reviews experimental work on the relationship between cataract and avitaminosis with respect to vitamin C, and tabulates his own results in treatment of cataract with vitamin C. Careful determinations were made of the concentration of the vitamin in the blood and urine, the methods of determination being described. The cases treated are divided into two groups, those with vision of 20/100 or better and those with vision less than 20/100. Of the former group of nine patients, six exhibited definite and three doubtful improvement. Of the latter group none were benefited.

The author concludes that in senile cataract there is a deficit of vitamin C and glutathione in the lens which increases as the lens opacity progresses; that this deficit may be demonstrated in the blood and urine; that, if the cataract is not advanced, benefit may be expected from ingestion of some source of vitamin C either orally, intravenously or by conjunctival instillation; and finally that there is a little hope of success from this method of therapy in advanced cases. Edward P. Burch.

Hoffmann-Rötzel, F. W. Erythropsia of aphakics. *Zeit. f. Augenh.*, 1938, v. 95, Sept., p. 323.

The aged author, who had both eyes operated upon for cataract when he was sixty years old, has had ample opportunity to observe erythropsia. He describes in detail his observations of color phenomena. He feels sure that erythropsia is not a phenomenon of excessive illumination as claimed by some, but depends on an achromatism which results from dispersion of light rays. The cause is purely physical and depends on the presence of an excess

of red rays in the light of the rising and setting sun and that reflected from the snow.
F. Herbert Haessler.

Laval, Joseph. Bilateral congenital ectopia lentis with arachnodactyly (Marfan's syndrome). *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 371-374.

After a brief résumé of the various signs and symptoms of this syndrome, two cases with this condition are reported. The author discusses the terminology and suggests that the term dysmesdactyly be adopted when the chromosomes concerned with mesodermal tissue are involved and dysmesectopia when the ectodermal tissue is also affected.
J. Hewitt Judd.

Purtscher, Ernst. Clouds of crystals in the clear senile lens-nucleus. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 358-366.

Among seven patients, between 65 and 80 years of age, there were observed in the otherwise clear sclerotic lens-nucleus collections of very fine crystals, needle- or plate-shaped. In the beam of the slitlamp, they varied from red to green in color. The position of the crystals in the lens nucleus differed, but they were generally more numerous in the vicinity of the lens axis near the surface of the nucleus.

H. D. Lamb.

Rosner, L., Farmer, C. J., and Bellows, J. Biochemistry of the lens. 12. Studies on glutathione in the crystalline lens. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 417-426.

Evidence is presented indicating that the difference in potential between the cortical and nuclear portions of the lens, found by potentiometric studies, is due to a change in the concentration of glutathione. Studies of the concentration of glutathione in the lens indi-

cate that the concentration of the nucleus remains relatively constant while that of the cortex varies significantly with age. When animals were fed galactose, the glutathione in the lenses diminished. In young animals the appearance of cataract followed shortly after the loss of glutathione, while in older animals such a loss might occur long before the appearance of opacities. The sharp change in potential found with small variations in the glutathione-beta crystalline ratio may be a more sensitive method than actual chemical determination for estimation of glutathione when it is present in small quantities.
J. Hewitt Judd.

Zeiss, Erich. Lens changes from the action of ultrasound waves on extracted cattle lenses. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 301-324.

Ultrasound waves being those in the air of more than 35,000 alternations per second are not transmitted to the human tympanic membrane. Ultrasound waves in this experiment are produced by causing a disc of quartz to vibrate by subjecting it to a high frequency current of electricity. The extracted cattle lenses placed in Ringer's solution and subjected to the ultrasound waves for from two to twelve minutes present vesicle-like opacities deep in the cortex. Longer ultrasound waves produce coarser or larger vesicles in the lens. When normal vitreous humor from cattle is subjected to these waves, it is found to liquify.

10

RETINA AND VITREOUS

Allen, T. D. Detachment of the retina. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 307-314.

This review includes a summary of

the theories on etiology and of the types of treatment devised to correct these conditions by the surgeons having the greatest experience, especially Gonin, Lindner, and Arruga.

J. Hewitt Judd.

Bourne, M. C., Campbell, D. A., and Pyke, M. Cataract associated with an hereditary retinal lesion in rats. *Brit. Jour. Ophth.*, 1938, v. 22, Oct., pp. 608-613.

Attention was attracted, some three years previous to the compilation of this article, to rats affected with such cataract, the rats being in a research laboratory for breeding purposes and not for experimental procedure. The rats appeared otherwise well, and reproduced as expected. A hereditary factor was sought. A cataractous female rat with a litter of eleven was first received for study, and six generations of rats were bred and studied. The cataract appeared in successive generations. There were no deaths other than from middle-ear disease or "rat pneumonia." Diet and housing were all that should be expected for normal rat living. The progress of the cataract is described, age limitations for the various stages being noted. A definite cause has not been found. It is not due to disturbance of blood supply or from metabolic interference. The point that some abnormality in the vitreous body or in the lens capsule may be more directly to blame for the cataract than the retinal lesion itself is being more fully investigated. (See next abstract.) (References, figures.)

D. F. Harbridge.

Bourne, M. C., Campbell, D. A., and Tansley, K. Hereditary degeneration of the rat retina. *Brit. Jour. Ophth.*, 1938, v. 22, Oct., pp. 613-623.

(See preceding abstract.) There be-

ing few records of hereditary retinal defects in animals, the authors regard as of considerable importance this opportunity of studying the degeneration of such retinae through all stages. The first obvious appearance of the abnormality was at 21 days of age, while the terminal stage was noted at eighteen months or older. The degeneration is fully described through the various stages. A comparison of this hitherto unknown pathologic condition in rats with human retinitis pigmentosa is made, with the explanation that the resemblance is too close to pass unnoticed and unmentioned. (Figures, references.)

D. F. Harbridge.

Danielson, R. W., and Long, J. C. A case of retinal arterial occlusion with partial recovery. *Amer. Jour. Ophth.*, 1938, v. 21, Nov., pp. 1264-1265; also *Trans. Western Ophth. Soc.*, 1937, 4th mtg.

Dubois-Poulson. Oscillometry of the arteries of the extremities in thrombosis of the central retinal vein. *Bull. Soc. Franç. d'Ophth.*, 1937, v. 50, pp. 224-233.

The authors classify their cases into three groups, according to the oscillometric index. When the index was low, the presence of hypertension of the artery indicated diminution in caliber of the vessels, due to sclerosis. When the index was low, and the arterial pressure was normal, the subjects were young persons, who often complained of cold sensations, pallor of the extremities, and increased sweating. The author thinks that juvenile arteritis may account for these cases.

When the index is elevated in all four extremities, it is difficult to decide whether the trouble is vascular, or is caused by disturbed heart action. When the index is raised in the lower vessels

alone, its peripheral origin is undeniable. The index is elevated when there is vascular hypotony. It is augmented by hypertension.

Clarence W. Rainey.

Concilliis, Nicola de. *Retinal metabolism in narcosis*. *Boll. d'Ocul.*, 1938, v. 19, Jan., pp. 45-51.

The writer tested the effect of a narcotic of the uretan series on the retina of the ox. In different test tubes he put constant quantities of retina and methylen blue and phosphate in different concentrations. A solution of 1 to 5000 ethyl uretan was then added, while a physiologic solution was added in control tubes. The narcotic effect of the ethyl uretan was evidenced by the fact that five times as long was required for the retina to discolor the methylen. The results of the experiments are given in tabulated form, showing that the retina is highly sensitive to the narcotic action of the ethyl uretan. This is probably due to the fact that the retina is rich in lipoids.

Melchior Lombardo.

François, Jules. *Circinate degeneration of the retina and thrombosis of the macular veins*. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 54.

The author reports two cases in each of which the circinate degeneration of the retina followed thrombosis of the superior macular vein. He calls attention to the fact that a macular vein and not a more important branch of the central vein of the retina was thrombosed. The circinate degeneration began three or four months after the initial thrombosis, and on the opposite side. (2 illustrations, 21 references.)

J. B. Thomas.

Fritz. *The blood volume in the retinal vessels*. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, p. 209.

The blood volume in the retinal vessels appears as integration of all the factors affecting retinal circulation. The ease with which one can cause a granular current in the retinal vein is a measure of blood volume in the retinal artery. Physiologically, when one compresses the globe more and more, one sees in the retinal vein at a certain point a rapid current which is interrupted completely when the retinal artery collapses. After a certain pressure, M_n , corresponding to the index of suppleness of the artery, diastolic collapse of the artery is increasingly noticeable, whereas the amplitude of systolic pulsation decreases, to be effaced entirely at a pressure M_x . This progressive increase in pressure reduces the passage of blood in an arithmetical progression. It is as if the pressure were constant, with the cross section of the artery normal at M_n , and zero at pressure M_x .

If the volume of blood entering the retinal artery is large, the venous column is not fragmented until the pressure is near M_x , but if the volume of blood in the retinal artery is reduced from any cause, then fragmentation occurs in the vein at some pressure near M_n . The author uses as a criterion, the speed of venous globules of one disc diameter per second. He expresses the blood volume by the formula

$$D = k + k' \left(\frac{C.V.G. - M_n}{M_x - M_n} \right)$$

in which k and k' are constants, k being the volume when the fragmentation appears spontaneously in the neighborhood of M_n , and $k+k'$ being the volume when fragmentation occurs at M_x .

The normal value of blood volume in the retinal artery occurs when venous collapse coincides with the second half of arterial collapse, and averages 0.7. When fragmentation occurs in the first

half of arterial compression, a pathological condition is present.

Clarence W. Rainey.

Fritz. Functional examination of the circulation of blood in the retinal vessels. *Bull. Soc. Belge d'Ophth.*, 1938, no. 76, p. 45.

The author comments in detail upon the factors involved in an examination of the retinal circulation, such as degrees of pressure, differential pressure, caliber of the retinal artery, blood pressure in the retinal capillaries, and collapse of the artery. (2 tables, 25 references.)

J. B. Thomas.

Gandolfi, C. Bilateral blindness from anatomical and functional alterations in retinal circulation. *Rassegna Ital. d'Ottal.*, 1938, v. 7, May-June, pp. 287-300.

The author reports two cases of bilateral acute blindness occurring in elderly individuals, and which fall into the classification of occlusion of the central retinal artery. He discusses the affections of the retinal arteries from the point of view of etiopathogenesis and distinguishes two groups, functional and anatomical. The ophthalmodynamometer of Bailliant was used and the value of this instrument in such cases is stressed. Basing his data on clinical findings, and especially the study of pressure in retinal artery and vein, he shows that one case was functional and the other anatomical, that is, due to a lesion of the vessel wall.

Eugene M. Blake.

Genet, L., and Charpentier, R. Retinal spasm in fatal diseases, from lack of acetylcholine. *Bull. Soc. Franç. d'Ophth.*, 1937, v. 50, pp. 215-223.

The authors report treating with acetylcholine a 34-year-old man who had a

fatal angina pectoris. Their observations of the retinal arteries did not enable them to differentiate the grave forms of the disease. The views of physiologists are reviewed. The term "chemical transmitters" designates those substances which permit transmission of nerve impulses from a neuron to a muscular or glandular cell or to another neuron. The point of action of these substances is the point of junction. Two such substances are known. One is adrenalin, which acts on the sympathetic nerves; the other is acetylcholin, which acts on parasympathetic nerves. When acetylcholin is lacking, vascular spasm occurs. Acetylcholin was supplied in the hope of relaxing vascular spasm.

Clarence W. Rainey.

Gibson, G. G. Clinical significance of the retinal changes in leukemia. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 364-370.

This report is based on the study of 22 cases in which the clinical diagnosis of leukemia was confirmed in nine cases at autopsy and in seven additional cases by biopsy. The ophthalmologic diagnosis and prognosis of leukemia are discussed and attention is called to the close parallelism between the amount of hemorrhage in the retina and the degree of anemia which is associated with the leukemia. The evidence presented suggests that therapeutic and investigative procedures should be directed toward the anemia instead of the leukocytosis in the unsolved problem of leukemia. (Discussion.)

J. Hewitt Judd.

Klien, B. A. Retinitis proliferans. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 427-436.

Several cases are presented to show that on the basis of clinical and histo-

logic studies it is possible to distinguish two types of retinitis proliferans and to deduce from the location and appearance of the plastic lesions the nature of the primary disturbance. In the first type, the exudation of hemorrhage from the retina into the vitreous, caused by inflammatory or traumatic alterations of the retinal vessels, is a primary event, and organization of the extravasation leads to the formation of the strand and membranes. In the second type, the main factor in the production of the plastic lesions is a slow circulatory impairment due to degenerative vascular disease, with formation of new compensating anastomotic channels, with or without hemorrhages at first. The retinitis is produced mainly by disturbance of venous circulation due to sclerotic changes of neighboring structures and preëxisting unfavorable topographic anatomic relationship. The differential diagnosis between the two types is clearly outlined and illustrated by fundus drawings and photomicrographs.

J. Hewitt Judd.

Kurz, Otto. Clinical aspect and pathogenesis of nonmyopic detachments of the retina (fixed detachment, retinal cysts, retinal splitting). *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 326-357.

In fixed detachment of the retina, the retinal tear is not so important, the retina is often transparent and the detachment vesicle-like or flat. Where ruptures exist, they frequently occur as separations at the ora serrata. Cysts in the retina are the primary factor, resulting either from traumatic influence or from congenital defects of development. Twenty-two such cases are tabulated in two groups. There are further tabulated seven cases (one bilateral) in which vesicle-like detachment of the retina was associated with peripheral

choroiditis and was therefore apparently caused by inflammatory exudate. Among 27 cases of retinal detachment operated upon by the method of Weve (diathermy-puncture), 21 were healed.

H. D. Lamb.

Kurz, Otto. Eye changes in lupus erythematosus. *Zeit. f. Augenh.*, 1938, v. 95, Sept., p. 315.

In a 24-year-old woman with lupus erythematosus, eye complications appeared during the three or four weeks before death. A phlyctenule-like papule developed at the limbus in the left eye, and four or five white protruding spots overlying the blood vessels appeared in the foveal region of the left fundus, accompanied by minimal edema and an occasional minute hemorrhage. Two days later, similar lesions appeared in the right fundus. In sections from the eyes obtained eight hours post mortem, it was seen that the retinal lesions consisted of gangliform degeneration of the nerve fibers. These clinical and histologic findings in a patient suffering from a severe septic affection characterize simple retinitis septica. It may occur as a transient lesion and end in complete recovery.

F. Herbert Haessler.

Lijo Pavia, J. Vitreous humor, incarceration in one eye and deposits on hyaloid membrane of each eye. *Revista Oto-Neuro-Oft.*, 1938, v. 13, Jan., p. 15.

The author describes a cone-shaped vitreous condensation occurring in one eye and whitish deposits on the hyaloid membrane of both eyes, in 31-year-old syphilitic patient. Edward P. Burch.

Paton, R. T. Recurrent retinal and vitreous hemorrhages in the young—Eales' disease. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 276-285.

The clinical manifestations of this

condition are reviewed and two cases are presented showing quite different fundus pictures. Both recovered, one with normal vision in each eye, and the other with restoration of two thirds of his sight in spite of a partially vascularized vitreous. The fundus changes are shown by drawings.

J. Hewitt Judd.

Perera, C. A. Retinitis pigmentosa with "hole" in the macula. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 471-474.

The literature is reviewed and this combination is reported in a 16-year-old girl whose parents were first cousins. The macular lesion developed in one eye while the patient was under observation. The author suggests that both the peripheral and central degenerative lesions were the results of local vascular disease and retinal deterioration.

J. Hewitt Judd.

Trantas, Nico. Operation for retinal detachment by diathermy coagulation, after the method of Weve. Retinal tears without detachment. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 234-239.

Success of operation for retinal detachment with a tear depends upon the best possible measurement of the location of the tear, and closure of the tear. The author takes the position of the ora serrata as basis for measurement. This is obtained by transillumination of the globe, placing the cone of the Lange lamp upon the opposite end of the lid, and conducting the ophthalmoscopic examination through a pupil dilated with atropin. Scuffing of the cornea by use of the contact glass is avoided by turning down over the cornea the conjunctival flap which is made in order to lay bare the sclera over the operative site. Incisions of the sclera at the site of the needle punctures aid in

puncturing the softened eyeball. Among sixteen cases operated upon there were twelve cures, one was improved, and three not benefited.

The author reviews reports of five cases of tear without detachment, and adds case reports of five more such cases studied by himself.

Clarence W. Rainey.

Valois, Jeandelize, Drouet, and Lemoine. Recurrent retinal hemorrhage, and endocrine disturbances. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 267-280.

A nineteen-year-old woman, soon after the birth of her first child, had recurring hemorrhage in each eye, together with cessation of the menses. As long as administration of thyroid was kept up, the hemorrhages improved and failed to recur. Addition of hypophyseal substance to the treatment caused recurrence of the menses.

Clarence W. Rainey.

Vogt, A., Wagner, H., and Schneiter, M. Investigations on the orientation of the normal structural membranes of the vitreous. *Klin. M. f. Augenh.*, 1938, v. 100, Aug., p. 235.

From thirty observations on normal youthful persons, the authors conclude that in erect position of the head the orientation of the structural membranes of the anterior vitreous is determined by the force of gravity.

C. Zimmermann.

Wibo and Rans. Prepapillary floating opacity of the vitreous. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 11.

The authors report a case of prepapillary floating opacity of the vitreous observed in a girl nine years old having atrophy of both papillae and discrete

areas of choroiditis. This condition is said to occur exclusively in adults.

J. B. Thomas.

11

OPTIC NERVE AND TOXIC AMBLYOPIAS

Benedict, W. L. Optic neuritis and retrobulbar neuritis: etiology and treatment. *Jour. Michigan State Med. Soc.*, 1937, v. 36, Dec., p. 946.

Benedict reports 500 cases of definitely proved multiple sclerosis, in 15 percent of which there was complaint of visual loss as the first symptom. In 40 percent visual disturbances were mentioned as the second or third symptom. Etiology and treatment are discussed. Theodore M. Shapira.

Fonseca, Aureliano. Amaurotic family idiocy. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 343-351.

The author reviews briefly cases of this condition reported in Brazil. He records one more case in a child born in Brazil, whose ancestors four generations back were born in Germany.

Ramon Castroviejo.

Fonseca, Aureliano. Ocular disturbances produced by rachianesthesia. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 353-354.

The author reports the case of a woman 35 years of age on whom a laparotomy was performed under rachianesthesia. A year after the operation very marked diminution of vision occurred, gradually leading to blindness of the right eye and counting fingers at six feet for the left eye. Ophthalmoscopy revealed marked atrophy of both optic nerves, and the author believes that this atrophy was produced by the rachianesthesia.

Ramon Castroviejo.

Giqueaux, R. E. Hereditary atrophy of the papillomacular bundle. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, March, p. 111.

This article describes the occurrence of hereditary atrophy of the papillomacular bundle in a family. Points of resemblance and dissimilarity to Leber's optic atrophy are discussed in detail. Myopia of slight or moderate degree was found in most of those affected. The disease, occurring bilaterally, begins at an early age. It is characterized by pallor of the temporal segment of the nerve head and a cecocentral scotoma. Females are affected as well as males.

Edward P. Burch.

Kravitz, Daniel. Studies of the visual fields in cases of verified tumor of the brain. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 437-470.

The findings as to 23 cases of verified tumor of the brain are presented in four groups: tumors of the frontal lobe, 6 cases; tumors in the region of the chiasm and the midbrain, 8 cases; tumors posterior to the chiasm, 6 cases; and tumors of the posterior fossa, 3 cases. The visual fields in the fourteen cases in groups 2 and 3, which might be expected to present localizing defects, showed signs of definite localizing value in 86 percent. From a diagnostic standpoint, a correct negative field may be as important to the neurosurgeon as a positive one. Of the nine cases of tumor in the frontal and posterior fossa eight, correctly, showed no localizing defect. The value of the visual fields is evident, since neurologic examinations gave correct results in only 70 percent of these cases. It is urged that every patient with persistent headache or other signs suggestive of possible tumor

should have an examination of the visual fields. J. Hewitt Judd.

Luzsa, Endre. The influence of enucleation on the development of the optic canal. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 413.

In the living, the roentgenogram alone can demonstrate changes in the optic canal; and then only if compared with that obtained under equal circumstances for the other side. Luzsa studied this problem in 37 individuals, in each of which one eye had been enucleated—in four before the eighteenth year and in twenty after the twentieth year. In 15 further cases with enucleation between three and twenty years of age the canal on the side of enucleation was smaller than on the intact side, with one exception. The author found that the development of the optic canal terminated at about the eighteenth year. After enucleation before that time the development of the canal was retarded in consequence of atrophy of the optic nerve, and in the roentgenogram it appears narrow as compared with the healthy side.

C. Zimmermann.

Mueller, Friedrich. Atrophy of the optic nerve of unknown etiology. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 329-330.

The author reports such a case.

Samuels, Bernard. The histopathology of papilledema. *Amer. Jour. Ophth.*, 1938, v. 21, Nov., pp. 1242-1258.

Sloan, L. L., and Woods, A. C. Perimetric studies in syphilitic optic neuropathies. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 201-253.

After a historical survey, the authors report the field defects in a group of 56 patients with primary syphilitic optic

atrophy, which were of four separate types: (1) concentric contraction of the peripheral field associated with late loss of vision; (2) sector-shaped, or nerve-bundle, defects, with which loss of vision might be early or late, depending on the involvement of the papillomacular bundle; (3) central or cecentral scotoma with normal peripheral fields, associated with early loss of visual acuity; and (4) central or cecentral scotoma with defects in the peripheral fields, also associated with early loss of vision. Central or cecentral scotoma was found in 53 percent of the cases of primary atrophy of the optic nerve. These studies indicate that perimetric changes may antedate either visual failure or pallor of the disc, and that the site of the lesion responsible for the field defects is in the optic nerve rather than in the chiasm or posterior to it and is probably a peripheral and interstitial neuritis with secondary degeneration. J. Hewitt Judd.

Vail, Derrick. Optochiasmic arachnoiditis. Importance of a mixed type of atrophy of the optic nerve as a diagnostic sign. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 384-394.

Study of the cases reported in the literature, associated with the clinical findings in two personal cases reported in detail, suggests that the involvement of the optic nerve is a combination of papilledema and simple atrophy. One or the other may predominate and the resulting atrophy will take on a mixed character. This appearance, in which the outline of the disc is sharply defined and the lamina cribrosa is visible, but the caliber of the vessels is markedly reduced, is highly suggestive if not pathognomonic of arachnoiditis involving the chiasm. Recent evidence indicates that encephalitis, multiple

sclerosis, other demyelinating diseases, sinusitis or focal infections, and optochiasmic arachnoiditis may be closely allied factors in producing retrobulbar optic neuritis and may be different manifestations of a single pathogenic process such as thrombosis in the venous system of the nerve tissue. (Bibliography.) J. Hewitt Judd.

Vidal, J., and de Farias, N. Treatment of optic-nerve atrophy by inoculation of malaria. *Trabalhos do Primeiro Cong. Brasileiro de Opth.*, 1936, v. 1, pp. 325-327.

The authors obtained marked improvement of vision in a single case so treated. The treatment should include iodides and bismuth.

Ramon Castroviejo.

12

VISUAL TRACTS AND CENTERS

Custodis, Ernst. Anatomic investigation and clinical observations on the syndrome of pterygopalatine-fossa lesions. *Zeit. f. Augenh.*, 1938, v. 95, Aug., p. 259.

Isolated synchronous and homonymous paralysis of the second ramus of the trigeminal nerve and of the abducens does not indicate a tumor of the pterygopalatine fossa. A tumor in this situation cannot involve these nerves by means of such pressure or infiltration without including the neighboring oculomotor nerves. The injury is caused by a malignant neoplasm which arises in the epipharynx and traverses the root of the pterygoid process. In the author's case, with further extension along the base of the cranium, destruction of the apex of the petrous portion of the temporal bone produced paralysis of the sixth nerve. Other fibers frequently involved are the secre-

tory fibers of the lacrimal gland, the third branch of the trigeminus, and the sympathetic fibers.

F. Herbert Haessler.

Genet, L., and Rosnoblet. Blindness without ophthalmoscopic signs in an infant; congenital form. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 240-246.

The authors report the case of a thirteenth-month-old infant whose parents had noted lack of vision when the infant was six months old. There had been no previous local or general diseases. The results of the physical and laboratory examinations were negative. There were no external or internal abnormalities of the eyes. There was only a slight pupillary response to light. Agenesis of the intracerebral optic pathways was considered as a possible cause. Clarence W. Rainey.

Oliva, Roberto. Ocular symptoms in affections of the apex of the petrous portion of the temporal bone. *Trabalhos do Primeiro Cong. Brasileiro de Opth.*, 1936, v. 1, pp. 357-360.

The author discusses briefly the relation between the fifth and sixth nerves, and the affections of the apex of the petrous bone. The symptoms that most directly interest the ophthalmologist are produced by paralysis of the abducens and neuralgia of the trigeminus, the first condition being known as the syndrome of Gradenigo. The author reports two cases, and urges ophthalmologists to be on the lookout for characteristic symptoms.

Ramon Castroviejo.

Paiva, Aroldo. Suboccipital puncture from the ophthalmologic viewpoint in cranial injuries. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, Feb., p. 92.

Cisternal puncture for relief of in-

creased intracranial pressure complicating head injuries is advocated by the author. He believes it to be superior to lumbar puncture. A brief summary of four cases of head injury treated by suboccipital puncture is given. The author would extend this method of treatment to other types of intracranial hypertension which might give rise to optic-nerve changes.

Edward P. Burch.

Pesme, P., and Hirtz. Observations of the syndrome of Laurence-Bardet-Biedl. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 297-310.

The authors report their observations of four cases, three males and one female, all under the age of sixteen years, who presented the picture of obesity of the hypophyseal type—genital hypoplasia, waxy pallor of the discs, ashy-gray changes at the macula, and peripheral retinal changes, described as retinal degeneration without pigment. The symptom of polydactyly was absent. The authors were able to obtain marked improvement in one patient by multiglandular therapy.

Clarence W. Rainey.

Wauters, Marcel. A case of bilateral amaurosis following abortion. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 59.

The patient, 28 years of age, and three months pregnant, attempted abortion by intrauterine injection of a solution of soap. A few minutes after the injection she became unconscious and vomited. A few hours later, upon regaining consciousness in a hospital, she declared that she was totally blind. The same night she expelled two fetuses 5 cm. in length. The loss of blood was not severe. In a week her vision had returned to normal. The author attributed the amaurosis to intoxication

caused by the absorption of soap by the uterine mucosa. In discussing the report Coppez stated his belief that the amaurosis had been simulated. (13 references.)

EYEBALL AND ORBIT

Auffinger, Erwin. Contributions to a solution of the problem of implantation of spheres after enucleation. *Zeit. f. Augenh.*, 1938, v. 95, Aug., p. 241.

Of 58 implants of bone, more than 49 were retained, and the result was considered satisfactory in all but eight of these. Nevertheless, for several reasons, the author discontinued the use of a bone sphere. The least of these was persistently irritated conjunctiva with copious tearing and mucopurulent exudate which might last for months. Sometimes the implant, although retained, became exposed through pressure atrophy and necrosis of the tissues. When a bone sphere had to be removed, it was found to be traversed by organized granulation tissue, and excision was extremely difficult. Local anesthesia was usually inadequate.

In six patients, the author implanted cartilage, but in four of them the sphere was extruded. In the end, spheres of amber were considered the most satisfactory. They are readily sterilized, are well tolerated by the tissues, resist absorption, and are easily made in any required size. A 15-mm. sphere weighs 1.5 gm. When amber spheres are extruded, they come away easily and cause no injury.

At the time of enucleation, the author threads all four rectus muscles on a single suture before cutting them. A special speculum with eight hooks helps keep the suture from becoming entangled. If this suture is tied as a

purse string, it forms a muscular stump which is useful even when the implant is lost.
F. Herbert Haessler.

François, J. Voluminous bony tumor of the external wall of the orbit, the great wing of the sphenoid, and the temporal fossa. *Bull. Soc. Franç. d'Ophth.*, 1937, v. 50, pp. 281-296.

A 45-year-old woman presented herself because of progressive exophthalmos of the right eye and swelling in the right temporal fossa. There was X-ray evidence of a large bony tumor. No operation was done.

Clarence W. Rainey.

Friede, Reinhard. A practical chalazion suture. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 325.

Where bleeding persists after excision of the chalazion through the skin, the author recommends a double-armed suture at each side of the wound, passing through skin, orbicularis muscle, and tarsus, tightened and tied.

H. D. Lamb.

Groenouw. A case of spontaneous orbital hemorrhage. *Klin. M. f. Augenh.* 1938, v. 101, Sept., p. 420.

On March 8, 1938, a woman aged 61 years came on account of sudden amaurosis of the hitherto perfectly healthy left eye, with headache and vomiting. There was ecchymosis under the skin of the lids, and bloody discoloration of the lower half of the ocular conjunctiva; with exophthalmos upward and limited motility. The pupil did not react directly to light, but did consensually. The fundus was normal, but vision was limited to light perception. Two weeks later the lateral half of the optic disc was pale, and after six weeks more the whole disc was completely white and the visual field

concentrically contracted. The condition was undoubtedly caused by a hemorrhage into the orbit due to a local affection of the orbital blood vessels.

C. Zimmermann.

Jaeger, Antoine de. Notes on certain cases of infection of the orbit. *Bull. Soc. Belge d'Ophth.*, 1938, no. 76, p. 63.

The writer classifies infections of the orbit according to Birch-Hirschfeld, as follows: (1) inflammatory edema of the orbit; (2) inflammation of the bony wall and periosteum of the orbit, especially in connection with sinusitis; (3) phlegmon of the orbit or orbital thrombophlebitis; (4) syphilis and tuberculosis of the orbit; and (5) tenonitis and pseudo-inflammatory tumors. Several case histories are reported illustrating these various types of infection. Two cases of retrobulbar phlegmon followed dacryocystorhinostomy done for acute dacryocystitis. In the discussion this procedure during the acute stage of a dacryocystitis was criticized, as was also simple extirpation of the sac in like circumstances. (4 X-ray plates).

J. B. Thomas.

Krause, A. C., and Weekers, R. Inositol in the ocular tissues. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 299-303.

Inositol was found in all tissues of the globe, with the possible exception of the vitreous. It was relatively constant in concentration in the different types of tissue but varied in different tissues. Concentration was high in the lens and in the optic nerve. It is thought that inositol may be a stable form of metabolite in the tissues which have no glycogen or only a small amount of it.

J. Hewitt Judd.

Kurz, Otto. Blood cyst of the orbit. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 405.

A girl aged seventeen years had noticed three weeks previously a sudden swelling and blue discoloration of her left upper lid, with exophthalmos, pain, and diplopia. At the nasal side of the eyeball an elastic movable resistance could be felt. The optic disc was indistinct, about five diopters prominent, with peripapillary edema. and vision 6/12. A bluish cystic tumor was extirpated from the depth of the orbit. It was a hematoma with a wall of connective tissue and with a vascular convolution at its posterior end. It was interpreted as the product of a thrombus in the ectatic venous convolution, caused through stasis during strenuous work, to which adenoid vegetations may have contributed as a respiratory impediment. The eliciting factor may have been vasomotor insufficiency during the menstrual cycle.

EYELIDS AND LACRIMAL APPARATUS

Fazakas, Alexander. Congenital symmetric ocular anomalies. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 257.

In investigating anomalies of the tear passages the author found numerous disturbances of development in the upper part of the lacrimal drainage tubes and around the whole palpebral opening. These he describes in detail.

C. Zimmermann.

Gernet, R. Remarks on the Blaskovics ptosis operation. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 422.

The simplified method described removes the deformities without resorting to implantation of auricular cartilage, regarded by Blaskovics as the only possibility for correcting such conditions.

C. Zimmermann.

Kreibig, Wilhelm. Plastic reconstruction of the lids. *Zeit. f. Augenh.*, 1938, v. 95, Aug., p. 269.

To make a new upper lid, the author uses a large pedunculated flap whose base is in front of the ear and which extends forward over and to the inner end of the eyebrow. It is important that the end of the upper incision near the ear shall lie at the level of the upper edge of the eyelid.

F. Herbert Haessler.

Lijo Pavia, J. Marked bilateral inflammatory ectropion. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, March, p. 149. (See *Amer. Jour. Ophth.*, 1938, v. 21, Dec., p. 1423.)

Mirič, B. A simple operation for entropion and trichiasis due to trachoma. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 381.

On account of the unsatisfactory results of the usual operations for entropion and trichiasis, the author devised a new method which in 161 cases gave good therapeutic and cosmetic results, and which is described in detail with illustrations. By stitching the separated upper part of the tarsus into the wound along the ciliary margin, the contracting effect of the levator is displaced to a lower point and its function increased, so that it supports aversion of the lid margin and cilia from the eyeball.

C. Zimmermann.

Mohamed, I. A. **Trachoma of the lacrimal apparatus.** Bull. Ophth. Soc. Egypt, 1936, v. 29, p. 7.

Since the lacrimal apparatus normally contains lymphocytic adenoid elements, a simple chronic inflammation may easily be mistaken for a specific trachomatous inflammation. Histopathologic studies give inconclusive evidence as to whether or not trachoma primarily attacks the lacrimal apparatus. A careful review of the literature is given. Photomicrographs of cystic dilation of the ducts of the lacrimal gland ascribed to gradual incomplete or intermittent obstruction of the lacrimal outflow following cicatricial processes in the conjunctiva are shown, as well as several photographs of follicular dacryocystitis corresponding to all stages of trachoma.

15

TUMORS

Appelmans. **Treatment of epithelioma of the eyelids.** Bull. Soc. Belge d'Ophth., 1938, no. 76, p. 75.

Basocellular or tubular epithelioma represents about 70 percent of these cases, the spino-cellular or lobulated form 15 percent, and the mixed form the remaining 15 percent. Epithelioma of the lid is preceded by a precancerous lesion in about 20 percent of all cases. The most important criterion for judging the gravity of a palpebral epithelioma is the age of the lesion, that is, its stage of evolution. The treatment described is that practiced by Maisin at the Cancer Institute of Louvain. Radium therapy is preferred and the

results were happy in 134 out of a total of 150 cases thus treated. As to the permanence of these favorable results, 7 had remained cured for at least 10 years, 6 for 9 years, 3 for 8 years, and 5 for 7 years. It is admitted that cataract may follow in a certain percentage of cases in which treatment has been energetic or prolonged but in view of the gravity of the disease the radium treatment should not be condemned. In the problem of cancer one must bear in mind that the individual tumor is not all. The study of precancerous lesions and the observation of multiple cancers show that the general condition must have a part in the genesis of cancer. Radium cures the local lesion but the cancerous tendency remains, so these patients must be kept under observation. In discussing the paper, Hubin stated that he had abandoned radium in favor of diathermy coagulation, using the unipolar method (without indifferent electrode). Weekers noted that diathermy was more convenient, was less costly for the patient, and left a scar comparable with that of radium. He insisted on the importance of the oculist directing the treatment of these cases, assisted by the radiologist and dermatologist. (16 references.)

J. B. Thomas.

Binkley, G. W., and Motto, M. P. **Primary epibulbar prickle-cell epithelioma.** Amer. Jour. Ophth., 1938, v. 21, Oct., pp. 1156-1158.

Birge, H. L. **Cancer of the eyelids, conjunctiva, and cornea. 2. Squamous cell epithelioma.** Arch. of Ophth., 1938, v. 20, Aug., pp. 254-270.

This condition was found in 59 out of 230 cases of epithelioma. It originated from the conjunctival surfaces, including the cornea, in 37 percent. Primary

corneal involvement occurred in 5 percent. The malignancy of most of the lesions was either grade two or grade three. There was a close correlation between clinical behavior and grade of malignancy; and recurrences were frequent. The average mortality of all types was about 12 percent. The grade of malignancy should be determined first, and treatment proportional with this rating should be carried out in order to prevent recurrences. The article includes eight case reports and photographs of various types of the tumor.

J. Hewitt Judd.

Capuano, Attilio Jose. Contribution to the study of sarcoma of the choroid. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 281-287.

The author reviews some cases from the literature and reports one in a patient 42 years of age. Ophthalmoscopic examination of the eye seemed to show characteristics of endophthalmitis, but finally a diagnosis of sarcoma of the choroid was made. Microscopic examination revealed a spindle-cell sarcoma.

Ramon Castroviejo.

Dunnington, J. H. Intraocular tension in cases of sarcoma of the choroid and ciliary body. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 359-363.

An analysis of 55 cases of intraocular sarcoma was made to determine the diagnostic value of intraocular tension in differential diagnosis between a serous detachment of the retina and one due to an intraocular tumor. In nine cases a definite secondary glaucoma had occurred. In 29 of the remaining 46 cases, the tension of the affected eye was found to be lower than that of the sound eye. In eleven the pressure was equal, while in six the affected eye showed a slightly higher

tension. The decrease, which varied from 2 to 10 mm. of mercury, was found as frequently when the tumor originated in the choroid as when it started in the ciliary body. The conclusion is reached that an initial drop in intraocular tension is the rule rather than the exception in the early stages of sarcoma of the choroid and ciliary body.

J. Hewitt Judd.

François, J. Aneurysmal dilatation of the ophthalmic artery. (Melanosarcoma.) *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 264-266.

Previously the author had reported an aneurysmal dilatation of the ophthalmic artery, with superior pseudohemianopsia, reduction of the visual acuity to 0.5, papillary stasis, and mild hypertension of the cerebrospinal fluid. Operation had revealed involvement of the optic nerve near the optic foramen, with a gray violaceous mass which was the artery doubled in volume. Subsequently the vision diminished, the retina became detached, and the tension rose. In the enucleated eye a pea-sized melanosarcoma was found.

Clarence W. Rainey.

Kronenberg, Bernard. Topography and frequency of complications of uveal sarcoma. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 290-298.

Most tumors are localized posteriorly and temporally. Eighty-eight percent of the 126 cases of uveal sarcomas were located in the choroid. There was an equal distribution between the two sexes and the average age was 52.6 years. The predominant type was the spindle-cell sarcoma. Almost all circumpapillary sarcomas caused detachment of the retina, and this complication occurred in more than 75 percent of all of these cases. The topographic

disturbance does not influence the frequency of glaucoma, which was found to be present in half of the eyes of this series. The site of the sarcoma has no bearing on the frequency of extra-ocular extension, which occurred in 36.1 percent. J. Hewitt Judd.

Lijo Pavia, J. Primary sarcoma of the choroid; early diagnosis; enucleation of eye having normal vision. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 276-279.

In a patient 27 years of age a small growth was found near the left macula. Visual fields taken at short intervals after the first examination showed the blind area to be growing larger. Microscopic examination of the enucleated eye proved the clinical diagnosis to be correct, the tumor being a melanosarcoma of the choroid.

Ramon Castroviejo.

Mathis, G. A case of leucosarcoma of the choroid. *Rassegna Ital. d'Ottal.*, 1938, v. 7., May-June, pp. 408-415.

The patient was a man of 71 years whose left eye had been blind for four years and had previously been treated for glaucoma. A small mass was seen in the anterior chamber in the lower nasal quadrant, at the root of the iris. Upon removal of the eye a mass was found on the outside of the globe, at the corresponding point, measuring 13 by 15 by 5 mm. When the globe was sectioned a tumor mass was found at the base of the iris, measuring 10 by 12 mm. Thus the extrabulbar portion of the tumor was greater than the intra-ocular. The cells were polymorphous and no pigment was found in them. At the point of perforation the scleral lamellae were widely separated. (3 figures.) Eugene M. Blake.

Mueller, F. Extirpation of a carcinoma of the lower eyelid and plastic repair of the defect. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 249-250.

The defect was covered with sliding skin flaps.

Stallard, H. B. A new technique for the application of radon seeds to the sclera in the treatment of glioma retinae. *Brit. Jour. Ophth.*, 1938, v. 22, Oct., pp. 604-608.

The technique described varies from that of Foster Moore as used at St. Bartholomew's Hospital. The cases of two children in whom the glioma was adjacent to the optic disc on the temporal side are described. In each case no increased irritation, no infection, and no sepsis followed the procedure, and there was no evidence of damage to the optic-nerve head or to the ocular media. The method is said to be technically simple and to be effective and free from complications. The radon seeds are embedded in a strip of dental stent shaped to the sclera at the site, and secured in place by sutures traversing the superficial layers of the sclera in front of and behind the equator. (Figures, references.)

INJURIES

Agnello, Francesco. Nasal syndrome and neuralgia of trigeminus through cornea injury. *Riv. Oto-Neuro-Oft.*, 1938, v. 15, Jan.-Feb., pp. 79-86.

A woman of forty years after a wound of the left cornea by her fingernail, became affected by intense pain around the corresponding orbit. The pain did not yield to the action of sedatives or hypnotics. The cornea showed

a linear wound whose character was not proportioned to the intensity of the other symptoms. A woman of 36 years was wounded on the left cornea by the fingernail of a baby. The same recurrent symptoms followed. In each the symptoms disappeared after treatment given to improve the general condition of the patient. M. Lombardo.

Alexandrov, V. V. The rationale of the set-up for the campaign against ocular traumatism. *Viestnik Opht.*, 1938, v. 12, pt. 2, p. 271.

A description of the official set-up of this department of ocular prophylaxis. Ray K. Daily.

Aliquò-Mazzei, Alessandro. Treatment of traumatic rupture of the sclera. *Boll. d'Ocul.*, 1938, v. 17, Feb., pp. 80-91.

Of four cases of indirect or contused rupture of the sclera, three were caused by the horn of an ox in farm workers. The fourth case was in a mechanic aged 19 years whose eye was struck by a fragment of a firearm. All four patients showed subconjunctival rupture near the limbus in the upper nasal segment of the globe, with subconjunctival dislocation of the lens. Conservative treatment is to be used, and enucleation or evisceration should not be resorted to sooner than a month after the injury. Surgical and prophylactic treatment are discussed. (Bibliography.)

Melchior Lombardo.

Avalos, Enrique. Electric ophthalmia as an industrial accident. *Rev. Cubana Oto-Neuro-Oft.*, 1938, v. 7, March-April, p. 41.

The effects upon the eye of electrical energy of varying intensities are described, and prophylactic measures suit-

able for workers exposed to such harmful effects are proposed.

Edward P. Burch.

Baltain, M. M. X-ray localization of intraocular foreign bodies. *Viestnik Opht.*, 1938, v. 16, pt. 1, p. 81.

A review of the various methods in use. The author prefers Comberg's method, in the use of which he replaces the contact glass by a prothesis of his own design. In doubtfully localized foreign bodies, he uses injection of radiopaque substances into Tenon's capsule. (Illustrations.)

Ray K. Daily.

Georgariou, P. M. Cholesterinosis bulbi. *Graefe's Arch.*, 1938, v. 139, pt. 1, pp. 32-49.

A girl 14 years old, who had been struck in the left eye with scissors ten years previously, had been totally blind for two years. The eyeball had recently shown much ciliary and conjunctival injection and a filling of the anterior chamber with a dense, white compact mass of rhombic cholesterine crystals. By paracentesis, these crystals were drawn off and their character confirmed. Thereafter the intraocular tension remained very low. Cholesterine crystals appeared again in the anterior chamber. This condition, to be distinguished from lipoidosis bulbi, is here described for the first time.

H. D. Lamb.

Gonçalves, Paiva. Penetrating orbital injury produced by fencing saber without lesion of skin or eyeball, and retention of metallic fragment in posterior cerebral fossa. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 237-248.

This trauma was sustained by an officer of the army, 29 years of age, during

a fencing lesson. The saber of his opponent entered the left orbital cavity through the conjunctiva, nasally to the eyeball, without injury to the globe itself. The injury was followed by slow pulse, vomiting, slight rise of temperature, severe headache, and semicoma. Locally there was marked chemosis of the eyelids, as well as subconjunctival hemorrhage more pronounced near the inner canthus. The eye was slightly deviated downward and outward. The fundus was normal. X ray showed to front view a foreign body which seemed to be located near the apex of the orbital cavity. The patient was operated upon under local anesthesia, an incision being made in the skin of the upper lid near the orbital margin, and over the nose. No foreign body was found, and the walls of the orbit appeared to be normal. A second X ray, showing a profile of the skull, revealed a foreign body located within the cranial cavity in the left occipital region. The cranial cavity was exposed by trephining a small flap of bone in the left occipital region, and a metallic foreign body 5 by 1 mm. was found near the opening and was easily removed. In a few months both eyes had normal motility as well as normal vision. Reconstruction of the path of the foreign body showed that the saber must have entered the left orbit through the conjunctiva near the inner canthus, penetrated the tendinous ring of Zinn, transversed the sphenoidal fissure, and passed through the whole cranial cavity to strike the occipital bone, where the point of the saber remained after the saber was withdrawn.

Ramon Castroviejo.

Grancini, L. E. Contribution to the study of ocular lesions from electric discharge, especially in relation to lens

changes. *Boll. d'Ocul.*, 1938, v. 17, Feb., pp. 92-111.

The face of a man of 45 years was swept by the flame developed from contact of an iron tool with a high tension wire. No shock was received. A few hours later his left cornea was slightly turbid, the iris hyperemic, the pupil slightly dilated and not reacting to light. The lens had a posterior capsular cataract and tension was 85 mm. (Schiötz.) Lens injury occurred in a man of 39 years, who on raising a hammer to within about 30 cm. of a high tension wire received a shock from which he remained unconscious for about six hours. The writer reviews experimental researches on electric cataract, and comes to the following conclusions: Electric cataract is the direct and immediate effect of the passage of the electric current through the lens. A co-existing uveal lesion favors formation of cataract. The cataract may reach maturity or the lens may remain partially transparent. (Bibliography.)

Melchior Lombardo.

Hertel, E. The closure of the wound by operation in perforating injuries of the cornea. *Graefe's Arch.*, 1938, v. 139, pt. 1, pp. 1-16.

The author agrees with Kuhnt that where there is a central, straight, perforating corneal wound with smooth sides and of an obliquity up to 3 mm., in the absence of conjunctivitis or tear-sac disease, no operative procedure is indicated. In the overwhelming majority of the author's cases, however, there was present a large wound with gaping and partly displaced wound edges and frequent prolapse of the iris. Operation was then necessary to close the wound and consisted of corneal suture or conjunctival flap, or both. In corneal suture, the thread does not pene-

trate the entire thickness of the cornea but only to the junction of its middle and posterior thirds. Nine illustrations taken from sections through healing corneal wounds, clearly show the approximation of the wound edges obtained by corneal suture or conjunctival flap. H. D. Lamb.

Kamel, Sabri. A case of traumatic total depigmentation of the iris. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 156.

A case is reported in which large patches of iris pigment were scattered over the lens capsule, together with hundreds of minute pigment granules. There was a superficial opacity of the lens. The iris meshes were entirely normal and the pupil showed no synechiae. The iris was tremulous and vision was reduced to hand movements. These changes occurred within 24 hours after injury. Edna M. Reynolds.

Lazarev, E. G. A new system of protective lenses for workers. *Viestnik Opht.*, 1938, v. 12, pt. 2, p. 269.

The author describes a new design which consists principally of stenopeic slits, placed horizontally in one eye and vertically in the other. (Illustrations.) Ray K. Daily.

Medvedev, H. I. So-called consensual ocular reactions. *Viestnik Opht.*, 1938, v. 12, pt. 3, p. 338.

This is a report of tonometric curves of both eyes in 46 cases of traumatism to one eye. The conclusions are that the primary reaction to traumatism may be either hypotension or hypertension, depending on the complications. There is a reflex effect on the uninjured eye, the extent and duration of which depends on the reaction of the diseased eye. The most marked feature of the reflex changes is the increased amplitude of

the daily tension curve. There may also be an effect on the adaptation, corneal sensitivity, angioscotomata, and accommodation. Ray K. Daily.

Rapisardo, Dante. A rare case of detachment of the pars iridica retinae. *Boll. d'Ocul.*, 1938, v. 17, Jan., pp. 40-44.

A man of 23 years who had sustained a perforating wound of the cornea at the age of nine years showed a dense adherent leucoma at the 5-o'clock position. Lens capsule was incarcerated, and there was posterior synechia with adhesion of the upper part of the iris to the lens capsule. The pupillary area was in great part occupied by a membrane of the same color as the pupil. This formation evidently consisted of posterior layers of the iris which had become adherent to the lens capsule and had been brought down and held in that position by the part of the capsule included in the corneal scar.

Melchiore Lombardo.

Sherman, G. C. Ocular injury with an indelible pencil. *Viestnik Opht.*, 1938, v. 12, pt. 2, p. 277.

A six-year-old girl came to the clinic six days after perforating the right eye with an indelible pencil, a particle of which remained in the eyeball. The aqueous, the lens capsule, and the iris had a violet tint, the fundus was invisible, and vision was counting of fingers close to the face. The anterior chamber was opened and was irrigated with 1 to 1000 tannic-acid solution, and two drops of 1 to 1000 collargol were introduced. A fibrinous iridocyclitis followed, and the result was a quiet eye with an opaque cornea, and vision equal to light perception. Ray K. Daily.

Vila Ortiz, J. M. Case of traumatic cataract in rosette. *Trabalhos do Prim-*

eiro Cong. Brasileiro de Opth., 1936, v. 1, pp. 249-251.

The author has already reported five such cases, in all of which he found a history of trauma. The present patient had sustained a severe blow on the head 25 years previously.

Ramon Castroviejo.

Wiegmann, E. A case of spontaneous reattachment of a traumatic iridodialysis. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 423.

In a laborer a small traumatic iridodialysis became spontaneously reattached, showing that in small dialyses an expectant treatment may be indicated.

C. Zimmermann.

Wölfflin, E. On the time relationship of the occurrence of lens opacities after radiation with various wave lengths. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 321.

The varying time of occurrence of lens opacities after radiation with various wave lengths is not a uniform process which can be explained on a purely physical basis. The action of infrared and ultraviolet is a direct damage by absorption. Injuries by roentgen and radium rays are probably caused indirectly through the nourishing organ, namely the ciliary body. Otherwise the long latent period would not be physiologically conceivable, nor would it be logical that the most posterior parts of the lens should first become opaque.

C. Zimmermann.

Woodruff, H. W. Spontaneous extrusion of an extraocular foreign body (shot) with recovery of vision. *Amer. Jour. Opth.*, 1938, v. 21, Sept., pp. 1028-1029.

SYSTEMIC DISEASES AND PARASITES

Andrade, Cesario de. Complexity of the cervical oculo-sympathetic syndrome. *Trabalhos do Primeiro Cong. Brasileiro de Opth.*, 1936, v. 1, pp. 361-366.

Mention is made of the different ocular symptoms that take place in affections of the cervical sympathetic. Three cases are reported: one in which after an alcohol injection of the phrenic nerve the patient developed a typical Horner syndrome; one of trauma to the cervical vertebrae, with a syndrome of the posterior cervical sympathetic, including marked myosis and enophthalmos; a third in a patient with a tumor of the throat causing irritation of the cervical sympathetic with exophthalmos and marked mydriasis.

Ramon Castroviejo.

Busacca, Archimede. Worms and other intestinal parasites as cause of ocular affections, particularly uveitis. *Trabalhos do Primeiro Cong. Brasileiro de Opth.*, 1936, v. 1, pp. 289-290.

Intestinal parasites may produce a number of ocular manifestations, namely blepharitis, keratitis, conjunctivitis, uveitis, retrobulbar neuritis, and papillitis. Elimination of the parasites invariably cures the ocular manifestations.

Ramon Castroviejo.

Chojnacki, P. Experimental and clinical studies on focal infection of dental origin. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 288-300.

In ten cases of iritis and four of axial optic neuritis (two bilateral), one or more teeth with dead pulp were extracted. Cultures from the apices of the affected teeth showed in nine cases streptococcus viridans and in four cases

forms of streptococci other than viridans and hemolyticus. From 24-hour-old primary bouillon cultures in each case, intravenous injections were made into either two or four rabbits. Some degree of ocular infection followed in 24 rabbits and streptococci were isolated from the blood of 21 rabbits out of 37 inoculated. From an experience of over 25 cases of ocular disease due to dental infection, the author concluded that negative roentgen-ray findings in the teeth were not decisive and that a dead tooth root without a granuloma was much more dangerous than one with a granuloma. H. D. Lamb.

Dejean, C. Fundus changes in the rabbit in rabies. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 247-154.

Twenty rabbits were inoculated with rabies through a trephine hole in the skull. Phenomena observed were: loss of corneal reflexes and pupil reactions to light; paralysis of the lid muscles, and of the external muscles of the globe; loss of transparency of the cornea and vitreous; intense congestion of the optic nerve and of the retina. The retina offers a true picture of the intracranial changes in rabies.

Clarence W. Rainey.

Eissa, A. S., and Kamel, Sabri. Three cases of tuberculosis of the eye. *Bull. Ophth., Soc. Egypt*, 1936, v. 29, p. 188.

The first case reported is one of primary tuberculous conjunctivitis and dacryoadenitis in a girl of seventeen years, which improved under general treatment. The second case is one of conglomerate tuberculous choroiditis which perforated the sclera near the limbus. The patient, aged five years, was found to be entirely free from tuberculosis elsewhere. The third case

is one of cold abscess of the globe in a child of five years, who had pulmonary tuberculosis and died shortly after excision of the globe.

Edna M. Reynolds.

Gabriélidés, C. A. Filaria in the anterior chamber of the eye. *Ann.d'Ocul.*, 1938, v. 175, Aug., pp. 581-589.

Report of one case of filaria in the anterior chamber. Instillation of pilocarpine in an attempt to lock the parasite in front of the iris seemed to irritate it, and the organism was lost behind the pupil. Enucleation was then performed and the parasite identified as a filaria.

John M. McLean.

Hermans. The pathology of ocular affections of dental origin. *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, p. 155.

The reports of Fromaget, 1924, and Worms and Bercher, 1925, are reviewed. The author gives a detailed theoretical discussion of the manner in which various dental abnormalities and infections may cause ocular disease.

Clarence W. Rainey.

Klivanskaja, A. A. The eye as an indicator of congenital and acquired changes in children. *Viestnik Opht.*, 1938, v. 12, pt. 1, p. 116.

The author describes in detail the ocular symptoms of congenital syphilis, and hopes that very complete routine physical examinations of children will serve to detect, and to institute early treatment of, this disease.

Ray K. Daily.

Kreibig, W. Blood diseases and the eye. *Wien. med. Woch.*, 1938, July 11, p. 772.

Kreibig describes the eye findings in various diseases of the blood-forming organs, including the anemias, throm-

bosis, acute hemorrhage, leukemias, polycythemia, and agranulocytosis.

Theodore M. Shapira.

Meyer, F. W. Contribution to the syphilitic diseases of the eye. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 390.

A woman of 39 years was sent to a sanatorium with the diagnosis of right-sided scleritis and tuberculous keratitis. After a transfusion, she died suddenly from a thrombus in the carotid, which was mobilized by the transfusion and so induced embolism of the middle meningeal artery and cerebral hemorrhage. The autopsy revealed syphilitic mesaortitis and almost complete obstruction of the carotids, in connection with the roentgenological pulmonary findings, attributed to a luetic infection of about 10 or 15 years previously. But, the scleritis spoke for tuberculosis. The histologic changes in the eye are described in detail. The case shows the importance of seroreactions to lues, even in the presence of apparent ocular tuberculosis. C. Zimmermann.

Rosenblum, M. E. Our latest cases of cysticercus. *Viestnik Opht.*, 1938, v. 12, pt. 3, p. 349.

Brief case reports of thirteen cases treated during the last five years. Of these eight were subretinal, two pre-retinal, and three in the vitreous. In three of the subretinal cases the cyst was in the region of the macula. General examinations were made in nine patients; tenia solium was found in four, and eosinophilia in six cases. Localization was by the method of Gonin, verified by electrocoagulation under ophthalmoscopic control. All cases were operated upon; in eleven the cysticercus was extracted, and in two the attempt failed. Ray K. Daily.

Safar, K. Diabetes and the eye. *Wien. med. Woch.*, 1938, June 18, p. 685.

Safar discusses the various disturbances and changes that take place in the eye in diabetes. He states that symptoms are due only partly to disturbance in metabolism, blood-vessel changes also playing a part.

Theodore M. Shapira.

Schartz, S. E. Carbon-monoxide poisoning. *Viestnik Opht.*, 1938, v. 16, pt. 3, p. 370.

The symptoms of carbon-monoxide poisoning are very bizarre generally as well as relative to ocular manifestations. The author's case was unusually severe, with edema and ecchymosis of the lids, chemosis, exophthalmos, limitation of movement, superficial keratitis, and rise of intraocular tension. The final result was loss of vision in the right eye and recovery in the left.

Ray K. Daily.

Simoes, Elyseo. Heredity in ophthalmology. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 385-401.

After a long discussion on hereditary factors which play a role in ocular manifestations, the author reports six observations. The first is of a family of eight members, all having cataract. The second is of a small family in which there were four cases of infantile glaucoma. Consanguinity was found in the second instance. In the third family, of five persons, all had dyschromatopsia. In the fourth family, of 28 members in three generations, eight cases of albinism were observed. In the fifth family, 32 persons of three generations, there were twelve cases of albinism, and a history of consanguinity. The sixth family was of five persons in

which both parents and children were affected with myopia. The author concludes that there is a definite influence of heredity in ocular affections, consanguinity playing an important part in many cases. (63 references.)

Ramon Castroviejo.

Walker, J. R., and Walker, B. F. A specific treatment for herpes zoster. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 304-306.

The authors report that diphtheria antitoxin has proved to be a specific remedy for herpes zoster in the acute as well as in the chronic stage, usually giving relief from pain within 24 hours and preventing recurrences.

J. Hewitt Judd.

Weckert, Fritz. *Biology in ophthalmology*. Graefe's *Arch.*, 1938, v. 139, pt. 2, pp. 280-287.

A tuberculous inflammation of the retina or choroid resulting from bacillary emboli derived from the lymph glands at the hilus of the lung is an attempt with renewed energy to restore the normal state. Tuberculous and luetic infections of retina, uvea, and cornea correspond to similar infections of the cutis and the subcutaneous tissue of the skin.

H. D. Lamb.

Zobel. The treatment of headache and neuralgia by the oculist. *Zeit. f. Augenh.*, 1938, v. 95, June, p. 137.

The oculist need not send a patient away after prescribing glasses and determining that there is no cause for headache manifest in the fundus. Most headaches have their origin in a neuralgia of the trigeminal nerve. If pressure over the superior orbital margin causes pain or if the swollen nerve is palpable, the diagnosis of supraorbital neuralgia is certain. The author's

treatment consists of application of a galvanic current of two milliamperes for five minutes to each branch of the nerve. For supraorbital neuralgia the cathode is placed on the inner end of the superior orbital margin, the anode on the neck. A metallic taste confirms the passage of current through the nerve. Five daily sessions usually cure the patient completely.

F. Herbert Haessler.

Zolotnitskii, I. H. Malarial ocular complications in the Kiev region during the summer of 1935. *Viestnik Opht.*, 1938, v. 12, pt. 3, p. 377.

There were 68 cases classified as follows: keratitis herpetica 35, parenchymatous keratitis 2, herpes palpebralis 4, retinal hemorrhage 3, iritis 2, optic atrophy 1, dendritic keratitis 11, episcleritis 1, cyclitis 3, optic neuritis 1, convergent strabismus 1, vitreous opacities 4. The author urges that malaria be thought of in cases of obscure etiology, and that the melano-flocculation reaction be used in cases negative for the plasmodium. Ray K. Daily.

Leydhecker, F. K. Concerning the eye, from Rückert's "Wisdom of the

Brahmans." *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 271.

Quotations from a didactic poem on personal and general questions of life. C. Zimmermann.

MacCallan, A. F. The world-wide distribution of trachoma, excluding the Dominions, Colonies, and mandated territories of Great Britain. *Brit. Jour. Ophth.*, 1938, v. 22, Sept., pp. 513-541.

It is the purpose of the author in this lengthy presentation to give an approximate estimate of trachomatization throughout the world, exceptions being noted which have been previously outlined (see *Amer. Jour. Ophth.*, 1935, v. 18, March, p. 301). The use of the slitlamp not being possible in distant sections of the world, there must of necessity be an underestimate of trachoma actually existing in such regions. The article does not lend itself to abstract. D. F. Harbridge.

Mendoza, Rafael. The oculist and industrial accidents. *Rev. Cubana de Oto-Neuro-Oft.*, 1938, v. 7, March-April, p. 49.

The author cites some of the difficulties encountered in industrial ophthalmology. Edward P. Burch.

Meyerhof, Max. The history of trachoma treatment in antiquity and during the Arabic middle ages. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 26.

The Greek medical works which have come down to us show a knowledge of four stages of trachoma, of entropion and trichiasis but not of pannus. The Greeks knew different scraping manipulations not much inferior to those in use at present. As a treatment for trichiasis they excised the skin but not the tarsus, and made an intermarginal incision with transposition of the lashes.

The Arabs knew the connection of trichiasis and pannus with trachoma, and appreciated its contagious character. Their mechanical and operative treatment of trachoma was not very different from our own. The best description of trachoma and its treatment before the 19th century was written by Ali ibn Isa, an oculist of Bagdad in the tenth century. Edna M. Reynolds.

Schwichtenberg, A. H. The evaluation of orthoptic training for aviators. *Amer. Jour. Ophth.*, 1938, v. 21, Sept., pp. 980-990.

Sena, J. A. Some notes on the International Congress of Ophthalmology. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, March, p. 135.

The author discourses briefly upon the ocular disorders, chiefly trachoma, encountered in Egypt, giving a brief account of the ophthalmic hospital facilities. He also gives a résumé of the meeting of the International Organization Against Trachoma.

Edward P. Burch.

Vila Ortiz. Instruction and professional orientation of the visually defective. Creation of special schools. *Arch.*

de Oft. de Buenos Aires, 1935, v. 13, Feb., p. 71.

The author makes a plea for the establishment of schools for the visually handicapped in the Argentine. He believes that children whose vision is 2/10 or less in the better eye with or without correction would be greatly benefited by the establishment of such schools. The selection of students and instructors, and the method and conditions of instruction are outlined in some detail.

Edward P. Burch.

DEATHS

Dr. Alfred F. VanHorn, Plainfield, New Jersey, died September 30, 1938, aged 77 years.

Dr. Harry S. Hughes, Saint Louis, Missouri, died September 15, 1938, aged 56 years.

Dr. Anders G. Hovde, Los Angeles, California, died October 14, 1938, aged 62 years.

Dr. Frank Clifford Ard, Westfield, New York, died August 23, 1938, aged 74 years.

Dr. Allen Rupert Cunningham, Halifax, Nova Scotia, Canada, died July 3, 1938, aged 50 years.

Dr. Harry Sebastian Reger, Jamestown, New York, died July 14, 1938, aged 60 years.

MISCELLANEOUS

The American Board of Ophthalmology announces an important change in its method of examination of candidates for the Board's certificate. Written examinations will be held in various cities two months prior to the date of the oral examination. The first written examination will be on March 15, 1939. For further particulars see the editorial on page 85 of this issue of the American Journal of Ophthalmology.

Examinations will be divided into two parts. Candidates whose applications are accepted will be required to pass a written examination which will be held simultaneously in various cities throughout the country approximately 60 days prior to the date of the oral examination.

The written examination will include all of the subjects previously covered by the practical and oral examinations.

Oral examinations will be held at the time and place of the meeting of the American Medical Association and of the American Academy of Ophthalmology and Otolaryngology, and occasionally in connection with other important medical meetings. The oral examination will be on the following subjects: External diseases, Ophthalmoscopy, Pathology, Refraction, Ocular motility, Practical surgery.

Only those candidates who pass the written examination and who have presented satisfactory case reports will be permitted to appear for the oral examination.

Examinations scheduled for 1939. Written: March 15th and August 5th. Oral: Saint Louis, May 15th; Chicago, October 6th.

Applications for permission to take the written examination March 15th must be filed with the Secretary not later than February 15th.

Application forms and detailed information should be secured at once from Dr. John Green, Secretary, 6830 Waterman Avenue, Saint Louis, Missouri.

The University of Buffalo awards annually a gold medal for a work on an ophthalmologic subject. Recent awards went to Dr. J. Bellows of Chicago, Dr. Joseph Globus of New York, and Dr. J. Evans of Brooklyn. For details write to Dr. H. W. Cowper, 543 Franklin Street, Buffalo, New York.

A quarterly journal, The Journal of Social Ophthalmology, is now being published by the International Association for the Prevention of Blindness, with articles appearing in English and French. The address of the American office is 50 West 50th Street, New York City, with Lewis H. Carris the American correspondent.

The following new members were elected to fill vacancies on the Board of Directors of the National Society for the Prevention of Blindness, at the annual meeting of the Society, December 1, 1938: Dr. Thomas Johnson, ophthalmologist, New York City; Dr. John L. Rice, Health Commissioner of New York City; Professor Ira V. Hiscock, of New Haven, Connecticut, President of the National Health Council and Professor of Public Health at Yale University; Reverend John Gass, D.D., Rector of the Church of the Incarnation, New York City; Mrs. Hazel C. McIntire, of Columbus, Ohio, Director of Special Classes for the Visually Handicapped, Ohio State Department of Education. The following members of the Board of Directors were reelected for a three-year period at the annual meeting: Dr. A. J. Chesley, St. Paul, Minnesota; Mr. George C. Clark, New York City; Dr. J. Clifton Edgar, Greenwich, Connecticut; Dr. Edward Jackson, Denver, Colorado; Dr. Albert B. Meredith, Cranford, New Jersey; Mr. Preston S. Millar, New York City; The Rev. Alphonse M. Schwitalla, Saint Louis, Missouri; Dr. William Zentmayer, Philadelphia, Pennsylvania.

Portland, Oregon, is to have a Medical Library Building. In Science (issue of November 25, 1938) we notice that Dr. John E. Weeks has given \$100,000.00 to the University of Oregon Medical School. To this has been added an equal amount by the Rockefeller Foundation

and a sum secured from the Public Works Administration. These make a total of \$363,350.00, to construct a building for the Medical Library, with an auditorium to seat 600 for student and professional gatherings.

Harvard Medical School offers the following courses in Ophthalmology for the first half of 1939:

February 6-18. Ocular Muscles. This course includes neuro-anatomy and physiology of ocular muscles as an introduction to didactic and clinical work. It deals extensively with vertical deviations. Orthoptics not included. This course is given by Drs. Bielschowsky and Casten.

March 1-31. A course on The use of the slitlamp will be given by Dr. Betham; a course on External diseases of the eye by Dr. Gundersen; and a course on Ocular complications in general disease by Dr. King. These courses may be taken simultaneously.

April 10-May 6. Recent Advances in Ophthalmology. This course correlates pathology of the eye and clinical practice. It draws on all resources of the Eye Department of the Massachusetts Eye and Ear Infirmary; clinical, laboratory, and research. Although this course has pathology as a basis, it gives a cross-section of all work at the Infirmary. The pathology is given by Dr. Terry.

July. Visual Optics and physiology. This course is given by Drs. Ludvigh, Cogan, and Easton.

Beginners and general practitioners may take the course in Ocular complications in general diseases. All other courses listed are not open to beginners. Further information may be obtained from the Assistant Dean of the Medical School.

SOCIETIES

The Eye Section of the Philadelphia County Medical Society met on December 1, 1938. Dr. Aaron Brav presented Trachomatous ulcera-

tion of the cornea, treated with prontosisil. Dr. Temple Fay presented a moving-picture demonstration, in colors, Visual fields and other findings, including details of operation, and postoperative recovery of brain tumor. Dr. Walter I. Lillie discussed Dr. Fay's presentation.

The Canadian Ophthalmological Society, as newly instituted, held its first meeting in Montreal on August 24-25, 1938. The first president of the Society is Dr. Gordon Byers.

PERSONALS

Dr. Daniel B. Kirby, surgeon, and Dr. A. Egerhoffer, senior resident at the Institute of Ophthalmology of the Presbyterian Hospital in New York, journeyed to Santa Fe, New Mexico, to operate on a number of patients with eye diseases at the Procter Memorial Eye Clinic, cooperating with Dr. W. C. Barton of Santa Fe. The operations included a great number of cataract, glaucoma, strabismus, and pterygia cases. The clinic was conducted through the month of August, 1938.

Dr. William R. Fringer announces that his son, Dr. Robert C. Fringer, is now associated with him in the practice of ophthalmology, William Brown Building, Rockford, Illinois.

Dr. C. W. Rutherford, Indianapolis, was the guest speaker at the meeting in Toledo, Ohio, Eye, Ear, Nose, and Throat Club the evening of November 17th.

Dr. William Thornwall Davis, Professor of Ophthalmology, George Washington University School of Medicine, Washington, D.C., has been invited to participate in the Continuation Study Course at the University of Minnesota on January 16, 1939. Dr. Davis will lecture on Vertical muscle imbalance in its relation to convergent squint, and the Choice of procedure in muscle surgery.

HISTOLOGICAL STUDY OF THE EYES OF RABBITS CONGENITALLY INFECTED WITH SYPHILIS*

HIDETOSHI SHIGA, M.D.

Tokio, Japan

Up to the present time, animal experiments on syphilis of the eye have been chiefly limited to acquired syphilis. In view of the large rôle that congenital syphilis plays in the field of ocular disease also, I determined to conduct investigations in this field through rabbit eyes congenitally infected with syphilis.

Syphilis was induced by the method of Professor Takaki¹ as follows: Syphilitic material was inserted under the skin in the nose of female rabbits so deeply as to touch the bone, the skin was then sutured, and, after a few days when the wound was nearly healed, it was tapped gently every day so as to develop the lesion gradually. When the rabbits were thoroughly infected with syphilis they were mated. During the course of resulting pregnancy, 10 c.c. of syphilitic emulsion was, in a number of cases, injected intravenously through the aural vein, in order to secure a heavier infection.

Pregnancy in the normal rabbit lasts from 28 to 30 days, the number of young in a litter being 5 or 6, having a body weight of about 50 grams each at birth, increasing in two months to about 1,000 grams. In the case of our infected rabbits, however, the circumstances were very different. Abortion and premature birth, with deformity and dropsy of the fetus, were frequent. The general de-

velopment of the fetus was often deficient, and there was great variation in the size and weight of the individual fetuses in a litter. Even when the pregnancy carried through to full term the young often died soon after birth.

In some cases the fetus was extracted from the uterus at mid term so that the eyes could be examined. When this was done, the livers of the premature fetuses were taken out, and with the livers of those rabbits which died soon after birth, were emulsified and injected into the testicle of normal rabbits. A syphilitic lesion resulted in each case; that is to say, a tumor formation developed that was found on examination to contain spirochetæ.

The apparently healthy young were brought up under observation, but sometimes showed eye lesions. In such cases their eyes were removed and fixed in 10-percent formalin. This was also done with the eyes of all the premature fetuses and of the rabbits that died soon after birth. In the latter instances the eyes were removed with the neighboring organs, including lids, because the upper and lower lids adhered closely together.

My experimental material, including control fetuses and young from normal rabbits, is shown in table 1.

Histological study was carried out with

* From the Public Health Center. The author wishes to extend acknowledgement for the cordial guidance throughout the work rendered by his leader Prof. Dr. I. Takaki, of Tokio Imperial University.

- signifies days earlier than the expected pregnancy period.

* signifies the same mother rabbit whose number is given on the left, but the age of the young is different.

paraffin or celloidin sections of the eyeball, the sections being taken, in general, vertical to the natural position, but in some cases horizontally and in others tangential to the cornea. In the case of rabbits more than one month old, the section was made of the anterior half of the eyeball. Preparations were usually stained with hematoxylin and eosin, but when necessary Van Gieson's, or Unna-Pappenheim's, or bacterial staining was used. Spirochaetae pallida were examined with Jahnke's modified method of Levaditi's silver staining.

The larger eyes after being fixed in formalin were, in general, divided into two parts on a meridional plane, one for hematoxylin-and-eosin staining and the other for Jahnke's staining. Since the eyes of the fetuses were too small to be divided without injuring ocular tissues, the right and left eyes were used separately for these two types of staining.

The results of examination are shown in tables 2, 3, and 4.

The following is a summary and discussion of these results according to the three groups into which all cases have been classified.

I. Extracted fetus, premature fetus, and dead fetus at full term (tables 2 and 3).

The eyes of tiny fetuses extracted by laparotomy showed no particular pathological change and no spirochaetae could be seen in the eye nor in its neighboring tissues (table 2).

In the case of the eyes of premature fetuses and dead fetuses at full term, hemorrhage and retardation of development were frequent. Hyperemia and hemorrhage were often present in subcutaneous tissues of lids, extrinsic ocular muscles, neighboring tissues of lacrimal glands, conjunctiva, subconjunctival tissue, and in the cornea (fig. 1). Edema

TABLE 2
OCULAR CHANGES IN CONGENITAL SYPHILIS IN THE RABBIT

Group		I	II	III
No. of syphilitic mother rabbit		No. 15	No. 51	No. 11
Reinoculation		+	+	—
Age of fetus (days)		—13	—9	—4
Number of fetuses examined		5	7	7
Histological findings	Outer coat	Corneosclerotic coat is not yet developed. Lids are not formed.	Cornea and sclerotic separate from the surrounding tissues. Lids are developed but distinction between upper and lower lids is not formed.	Cornea and sclerotic are formed. Cornea is thin and young big nuclei in it are stained faintly. Karyokinetic figures can be seen. Upper and lower lids are formed but both lids adhere closely together.
	Intermediate coat	Uvea is not differentiated. At the layer where choroid will be developed later, capillary vessels can be seen filled with erythroblasts. Iris and ciliary body are not differentiated.	Uvea is differentiated. Layer of capillary vessels in choroid is formed, with erythrocytes.	Layers in uvea are differentiated.
	Inner coat	Outer nuclear layer in the retina is very thick. Posterior pole of lens is nearly attached to it. Capillary vessels in the retina and the vitreous are few.	Outer nuclear layer of the retina is still thick. Capillary vessels are formed in the retina and the vitreous.	Differentiation develops.
Pathological changes		—	—	In one case hyperemia and hemorrhage are seen in the subcutaneous tissue of lids and in the neighborhood of lacrimal glands. A few leucocytes in the subcutaneous tissues of lids and tarsal conjunctiva.
Spirochaetae		—	—	—

was sometimes seen in the subcutaneous tissues of the lids.

The tissues were much more delicate than those of the normal rabbit controls at a corresponding age.

Spirochaetae were found in three cases in the cornea or in the sclerotic (fig. 2), or in both the cornea and the sclerotic.

Cell infiltration was seldom found in the fetus. Changes in the corneal corpuscles, such as slight swelling and proliferation, are difficult to determine in the foetus, because the corneal corpuscles in the foetus are large and numerous in comparison with those in the adult, and no such changes were recognized, although care-

TABLE 4
OCULAR CHANGES IN CONGENITAL SYPHILIS IN THE RABBIT

Group	XIII	XV
No. of syphilitic mother rabbit	No. 78	No. 177
Reinoculation	—	—
Age (days)	62	56
No. of young	No. 3 (left eye)	No. 1 (right eye)
Clinical condition	Ulceration nearly in the center of the cornea and in the lower limbus. Ciliary injection. Purulent discharge. Edematous iris. Relief indistinct.	Thick corneal opacity from the upper limbus extending downwards and covering nearly $\frac{2}{3}$ area of the whole surface. Purulent discharge. Edematous iris. Relief indistinct.
Epithelium of the cornea	Just in the central part of the corneal swelling and proliferation of cells. Infiltration of pseudo-eosinophilic leucocytes. Otherwise degeneration of the epithelium.	Defect of the epithelium in wide area corresponding to corneal ulcer. Infiltration of pseudo-eosinophilic leucocytes.
Substantia propria	Subepithelial abscess. Infiltration of pseudo-eosinophilic leucocytes is remarkable especially in the anterior layer. Swelling and proliferation of corneal corpuscles. Leucocytes and cellular debris between laminae.	Infiltration with pseudo-eosinophilic leucocytes in the anterior layer. Also diffuse infiltration in the whole layer. Subepithelial change is remarkable. Spirochaetae were found. Swelling and proliferation of corneal corpuscles.
Descemet's membrane	Normal	Normal
Endothelium	Subendothelial (in the corneal parenchyma) infiltration of pseudo-eosinophilic leucocytes.	Normal
Limbus corneae	Infiltration of pseudo-eosinophilic leucocytes and round cells. Hyperemia.	Upper limbus: Edema, hyperemia. Hemorrhage. Prominent infiltration of pseudo-eosinophilic leucocytes. Lower limbus: Perivascular round-cell infiltration. Subepithelial vascularization.
Sclerotic	No remarkable change.	In the inner layer of limbus vascularization with perivascular round-cell infiltration.
Iris and ciliary body	At the foot of the iris and ciliary body: infiltration of pseudo-eosinophilic leucocytes. Iris: dilatation of capillary vessels.	Infiltration of pseudo-eosinophilic leucocytes. Hemorrhage at the foot of the iris and in the ciliary body.
Change of blood vessels	No remarkable change.	Thickening of walls of capillary vessels. Perivascular round-cell infiltration at limbus.
Remarks	Exudation at the angle of the anterior chamber.	Spirochaetae in the liver.
Spirochaetae	—	+

ful comparison was made with the control. No changes of any kind were seen in the blood vessels.

II. Young born at full term (tables 3 and 4).

The eyes of the young which died a few days after birth showed inflammatory changes, and the development was below normal both in the eyes and in general body development.

Fig. 1 (Shiga). Showing hemorrhage in the subcutaneous tissue of the lid, conjunctiva, subconjunctival tissue, and at the margin of the cornea; also the deficient development of several tissues in the eye of fetus no. 506 from syphilitic mother rabbit no. 12.

The usual body weight of the newborn young is about 50 grams, each member of a litter being nearly the same size. In two months they weigh 1 kg. In contrast to this, body weight of young no. 1 from the syphilitic mother rabbit no. 177 attained only 310 grams in 56 days.

Histological changes were frequent. In nearly all cases in this category there was diffuse infiltration of round cells in the limbus, and in those in groups X, XI, XIII, and XV infiltration was found also in one or more of the following—the

sclerotic, ciliary body, extrinsic ocular muscles, and iris. Infiltration of pseudo-eosinophilic leucocytes also was sometimes seen.

There were no changes in the blood vessels, such as thickening of the vessel wall, obliteration, or vascularization. In most rabbits of group XI perivascular infiltration was seen in the limbus, but it was not very remarkable.

There were two cases of prominent

Fig. 2 (Shiga). Demonstrating a spirochaeta in the sclerotic of fetus no. 9 from syphilitic mother rabbit no. 22.

keratitis which are described in full detail below (III).

The corneal corpuscles showed no significant change except in two cases in which proliferation and tumefaction were found. Granules faintly stained by hematoxylin were seen in the shape of a spindle or in a tiny lump between laminae of the substantia propria or around corneal corpuscles.

Spirochaetae were found in four cases out of 28 in this group although their presence did not always coincide with histo-

pathological changes as has been claimed by v. Hippel,² Clausen,³ Cattaneo,⁴ Schlimpert,⁵ Bab,⁶ and Waetzold.⁷

III. Cases of corneal ulcer (table 4).

(A) Young no. 3 from syphilitic mother rabbit no. 78 (group XIII).

On the 62d day after birth, the left eye exhibited corneal ulcer near the center of the cornea and the lower limbus. Ciliary injection and purulent discharge were

cornea to nearly two thirds of its depth from the external border, but less prominently in the deeper area. A few leucocytes were seen even in the neighborhood of Descemet's membrane. Corneal corpuscles showed proliferation and swelling, especially in the superficial layers. Just under the endothelium (parenchymal side), corresponding to the corneal ulcer, one or two layers of leucocyte infiltration were present. In addition to these epi-

Fig. 3 (Shiga). Showing patho-histological changes in the upper limbus of the right eye of young no. 1 from syphilitic mother rabbit no. 177.

Fig. 4 (Shiga). Showing the changes at the lower limbus of the same eye.

present. The iris was edematous and its outline was not distinct. The eye was enucleated on that day and subjected to histological study.

Near the center of the cornea, the epithelial cells were tumefied and proliferated, the epithelium was thickened, and infiltration of pseudo-eosinophilic leucocytes was seen. Subepithelially to this part, leucocytes and débris were darkly stained by hematoxylin. Near this part of the substantia propria, the infiltration of leucocytes was very prominent and resembled an abscess. Leucocyte infiltration was generally seen in the lymph spaces in the

thelial changes, the remaining epithelium showed degeneration.

At the limbus, infiltration of pseudo-eosinophilic leucocytes and round cells, and dilatation and congestion of capillary vessels were noted. Almost no change was seen in the deep layer of the sclerotic, but there were infiltration of pseudo-eosinophilic leucocytes and hemorrhage at the foot of the iris and in the ciliary body.

There was exudation at the angle of the anterior chamber. No change was seen in the vessel wall, there were no spirochaetae anywhere, nor could any bacterium be identified in the cornea by special

staining. The pathological changes observed showed that the process was acute.

(B) Young no. 1 from syphilitic mother rabbit no. 177 (group XV).

On the 56th day after birth, the right eye manifested corneal ulcer with purulent discharge. Dense opacity covered nearly two thirds of the whole cornea from the upper limbus, and the border between clear and opaque parts was very distinct. The iris was edematous so that

neighboring limbus (upper) showed remarkable pathological changes, such as proliferation of the epithelium with infiltration of pseudo-eosinophilic leucocytes, edema, dilatation and congestion of capillary vessels, hemorrhage, and marked infiltration of pseudo-eosinophilic leucocytes. Similar changes were seen in the deep layer of the limbus (fig. 3).

At the site of the epithelial defect, the uppermost layer of the substantia pro-

Fig. 5 (Shiga). Showing a spirochaeta in the cornea of this eye.

Fig. 6 (Shiga). Showing a spirochaeta in the liver of this rabbit.

its outline was not clear. Before enucleation, the aqueous humour of the anterior chamber and secretion from the conjunctiva were examined by dark-field illumination, but no spirochaeta was identified. The eye was enucleated on the same day, fixed in 10-percent formalin, and divided into two portions by vertical meridional section, one for hematoxylin-and-eosin staining, one for silver staining.

Three days later the rabbit died, and the left eye was then enucleated for examination, as were also the liver, spleen, kidney, and lung.

There were various histological findings. At the macroscopically opaque part of the right eye, the epithelium was torn out in a comparatively wide area. The

pria was thickened and looked like elastic membrane. Close to the limbus this fibrous tissue was interrupted by clumps of leucocytes and debris here and there. These bundles of fibrous tissues seemed to radiate into the substantia propria.

In the substantia propria itself, infiltration of pseudo-eosinophylic leucocytes in the lymph-spaces was prominent, especially in the anterior layer. The infiltration was rather diffuse and could be seen even in the part that appeared normal macroscopically.

Corneal corpuscles showed proliferation and tumefaction and were sometimes mixed with pseudo-eosinophilic leucocytes. Descemet's membrane was entirely normal, and no leucocytes could be seen

at the endothelium. Nor was there any pathological formation behind the cornea.

At the lower limbus infiltration of lymphocytes and plasma cells around capillary vessels was noticed (fig. 4). Vascularization could be seen directly under the epithelium of the cornea close to the limbus. Some capillary vessels in the limbus had thickened walls. Vascularization was also seen in the inner layer of the limbus, with perivascular round-cell infiltration and bundles of fibrous tissue running in irregular curls.

In the iris there were dilatation and congestion of blood vessels without any changes in the vessels themselves, but hyperemia and limited infiltration of pseudo-eosinophilic leucocytes were seen at the base of the iris and in the neighboring ciliary body.

With Jahnel's silver staining typical *Spirochaetae pallidae* were found in the cornea of the other half of this eye (fig. 5), but they were not numerous, at most one or two in a single section. They appeared more often in the superficial layer of the substantia propria than in the inner layer, but were not found at all in the epithelium, endothelium, nor in the limbus, although this showed definite pathological changes.

In the left eye, there was degeneration of the epithelium in the cornea; and at the limbus, infiltration of lymphocytes, plasma cells, and also a few pseudo-eosinophilic leucocytes were recognized.

There were no changes of Descemet's membrane, the endothelium, nor of blood vessels. *Spirochaetae* could not be identified in this eye, but those of typical shape were found in the liver (fig. 6).

DISCUSSION

The pathological changes at the lower limbus, remote from the ulcer, such as infiltration of lymphocytes and plasma cells, thickening of the vessel wall, perivascu-

lar cell infiltration, and vascularization directly under the corneal epithelium near the limbus and also in the inner layer of limbus with irregular running of fibrous tissue, demonstrate chronic inflammation. Such findings, however, as the infiltration of pseudo-eosinophilic leucocytes or a wide area of epithelial defect, are not observed in syphilitic interstitial keratitis in human beings nor in rabbits with experimentally induced syphilis.

It is interesting, however, to compare my findings with a few cases of interstitial keratitis in the human fetus reported by v. Hippel, Seefelder,⁸ and Cattaneo. The first two reported a defect of the corneal epithelium, while Cattaneo reported infiltration of leucocytes. Infiltration of leucocytes in the substantia propria and change of corneal epithelium in my cases resemble those described in the human fetus by these three investigators. I also found typical *Spirochaetae pallidae* in the cornea where little pathological change could be found.

It seems evident, therefore, that the pathological changes I have described can be considered syphilitic, and another type of interstitial keratitis, similar to that found in the human fetus.

CONCLUSION

One hundred forty-one eyes of 71 rabbits with congenital syphilis, ranging in age from very young fetuses to 93 days, were examined. Thirty-four eyes of 17 normal rabbits of corresponding ages were taken as controls. The conclusions are as follows:

1. Congenitally syphilitic rabbits are very liable to be born prematurely by abortion. Even if born at full term, they often die soon after birth. Their general development is below normal, and the development of ocular tissue is deficient as compared with that of normal rabbits.

2. Pathological changes noted are as

follows: (a) In the premature fetus and dead fetus born at full term—edema in the subcutaneous tissue of both lids; hyperemia and hemorrhage in the subcutaneous tissue of both lids, extrinsic ocular muscles, in the neighborhood of the lacrimal gland, conjunctiva, subconjunctival tissue, and the cornea.

(b) In the young which died shortly after birth—infiltration of round cells in the limbus, the sclerotic, the iris, the ciliary body, and extrinsic ocular muscles.

(c) In two young (aged 2 months) with corneal ulcer—in one of these I found spirochaetae in the cornea. Also prominent cell infiltration (pseudo-eosinophilic leucocytes) could be seen, especially in the anterior layer of the substantia propria, accompanied by a wide area of epithelial defect. The limbus (remote from the ulcer) showed such syphilitic changes

as perivascular cell infiltration, vascularization directly under the corneal epithelium near the limbus, and also in the inner layer of the limbus, with irregular curling of fibrous tissue, thickening of capillary vessel walls, and other changes.

Epithelial defect with subepithelial change is suggestive of a few cases of keratitis of the human fetus (congenital syphilis cases, or those supposed to be such) reported by H. v. Hippel, Reis,⁹ Cattaneo, and Seefelder, and my case is identified as a special type of interstitial keratitis, occurring in congenital syphilis of the rabbit, somewhat different from that in acquired syphilis.¹⁰

3. *Spirochaetae pallidae* were found in the cornea and the sclerotic, sometimes accompanied by pathological changes, sometimes not.

LATE RESULTS IN RETINAL-DETACHMENT OPERATIONS*

DOHRMANN K. PISCHEL, M.D.

San Francisco

The true value of any operative procedure can be estimated only by reviewing the results after a period of time has elapsed. This is especially true in the case of such a new and radical procedure as is employed by the various operations for the cure of retinal detachment.

The question that naturally comes up is whether the eyeball can stand such radical surgical insults as are suffered in a diathermy operation and, if it does withstand the immediate dangers, are there any late after effects which eventually negate the apparent immediate successful outcome.

Such possible late results are: (1) re-appearance of the retinal detachment; (2) degeneration of the macula; (3) atrophy of parts of the retina; (4) optic atrophy; (5) scleral ectasia; (6) troublesome hyperphoria; (7) most important of all, development of cataract.

Weve¹ reported a very complete résumé of the results of operations for retinal detachment at the Utrecht Eye Clinic. However, in this paper he gave no detailed report of the late results. Weve made some very valuable suggestions regarding comparative statistics, giving several broad classifications which, if adhered to, would enable one to compare fairly accurately statistics of different types of operations from different operators. It is to be hoped that such a classification will be generally adopted. He classifies as complicated the following types: (1) aphakia, or with luxated lens; (2) macular hole, or perimacular or peripapillary tear; (3) nystagmus; (4) mac-

rophthalmus or other congenital abnormalities; (5) glaucoma; (6) cases in which operation was unsuccessful elsewhere.

All others he calls "uncomplicated," although many are admitted to be very difficult.

Surveys of the end results of retinal detachment operations were also reported by F. Ramach,² covering all the differently operated-on eyes at Lindner's Clinic in Vienna. He reported a total of 77 permanent cures (50 percent) out of 159 cases, many of them "complicated," but did not go into details concerning the condition of the eyes at the time of re-examination. He mentions atrophy of the globe and complicated cataract among the unsuccessful cases, but does not give any statistics regarding the healed ones.

It seemed important to seek an answer to these questions as they applied to the diathermy operation for detachment, which is the one chiefly used in the United States. While not comprising so large a material as others have reported on, I felt that the statistics from 63 unselected consecutive cases with 37 cures—that is, 58 percent—of over a year's duration would be valuable. Therefore I reexamined as many of the patients with retinal detachment that I had successfully operated upon as could come to San Francisco. A few others were examined by local physicians in their home cities, to whom I am very grateful, and others have answered by mail as to their present condition. Unfortunately, five of the cured patients could not be reached, so only 32 are entered in this study. For this survey only those patients were reexamined who had been operated upon at least one year ago.

* From the Division of Ophthalmology, Stanford Medical School. Preliminary report of this paper was read before Pacific Coast Otoophthalmological Society, Salt Lake City, May 26, 1937.

It was felt that the most recent cases were too fresh to give a reliable picture of late conditions. All had been operated upon by the Safar method of multiple diathermy puncture. While in the earliest cases only one line of pins had been inserted, in all later cases double rows of pins were used. Transcleral treatment (Larsson) or application of bident electrode (Walker) was also employed to supplement the above. Patients were kept in bed with binocular bandage for two weeks postoperatively. They then wore stenopeic glasses for two months. When these were discarded the patients resumed their normal activities.

RESULTS

The result of the reëxamination furnished the facts from which I was able to answer all the questions enumerated above. These answers were favorable, surpassing the most optimistic expectations. They are briefly discussed in the following paragraphs.

Reappearance of detachment: Of the 32 cured patients who were reëxamined, all have stayed cured for a minimum of at least a year. Included in this are four who were operated on twice. In these four cases, the detachment reappeared within three months of the first operation; the patients were successfully operated upon a second time, and the retinas have remained attached since then. A fifth patient was operated upon three times before being cured, each recurrence coming well within three months of the last operation. No detachments recurred that had remained cured over three months. It may therefore be said that if a case is cured for a period of three months no relapse is to be anticipated.

This statement necessitates a brief explanation of the length of after-care of our patients. They wear stenopeic spectacles for two months after the operation,

as mentioned before, and then discard them. Their eyes therefore resume normal rotations at that time. Therefore any retina which had remained in place merely because of this immobilization of the eyes, and not because successfully reattached, would very quickly again detach itself and once again appear as a regular retinal detachment. It might therefore be better to figure the duration of a cure from the date when the eyes resume their normal movements, rather than from the date of operation, as some operators restrict their patients in the free use of their eyes for many months postoperatively. One ophthalmologist even has them wear stenopeic glasses for a year! This prolonged period of convalescence might explain some of the relapses reported as occurring after a "cure" of many months' duration.

A further interesting fact of this study is a cured one-eyed patient, whose original detachment had occurred two weeks after a moderate blow on the head, who subsequently suffered a severe contusion to the head many months after the operation. No detachment occurred this time, giving added proof that the retina, once firmly attached, is as well as before the operation, or even better.

Another patient, six months after the operation, fainted, striking her head on a basin, yet suffered no relapse, again demonstrating the efficacy of the operation.

Degeneration of the macula: The vision in all but three of these cases has remained at the best level to which it returned after the operation. In one of these three cases in which the vision became worse there was a traumatic cataract, due to a perforating injury with iris prolapse. Here the traumatic cataract developed further, so that the vision was greatly reduced. Another was also a traumatic case in which a posterior subcapsular lens

opacity is developing. The third was a complicated cataract, to be described later. The fact that in all other cases the vision did not deteriorate shows that there was no late degeneration of the macula.

Atrophy of the retina: No late atrophy of the retina was noted. The operated-on areas showed typical pigment hypertrophy and irregular choroidal atrophy in the region of the pin punctures, but elsewhere the fundus was normal. The marked pigment hypertrophy seen a few months after the operation usually diminished considerably after the lapse of a year. Ophthalmoscopic examination further revealed the interesting fact that the retinal vessels could almost always be traced crossing over the atrophic areas undistorted, to be seen disappearing in the periphery in a normal manner. This is interesting proof of the lack of destruction of all layers of the retina. While the pigment epithelium and even the rods and cones may be destroyed, the inner layers of the retina are preserved. The fact that the retina did not atrophy later is further borne out by the tests of the visual fields. The visual fields remained constant, no shrinkage from the immediate postoperative findings being noted in any case but one. In cases in which very extensive areas far back from the limbus had been operated upon in one part of the retina, a slight constriction of the field corresponding to this area would have been found immediately after the operation, and this change remained constant but did not increase. The only exception to this rule was in the case of the one patient who was operated upon three times: a field defect developed a few months after the last operation in the area which had been operated upon twice, and here the fundus showed marked choroidal changes.

Optic atrophy: No optic atrophy could

be noted objectively, with ordinary or red-free light.

Ectasia of the sclera: Examination of the sclera in the operated-on region and of the fundus revealed no case of ectasia of the sclera.

Troublesome hyperphoria: The possibility of a marked permanent hyperphoria remaining in cases in which a complete tenotomy of a vertical rectus had been performed at the time of the operation was studied.

There were 16 cases of complete tenotomy of a vertical rectus in two-eyed patients and 2 cases of such a tenotomy in patients with monocular conditions. These latter two are, of course, disregarded. The muscles were all resutured to the muscle stump. Of the 16 cases of complete tenotomy in two-eyed patients, 10 had no hyperphoria resulting from the operation or so little, 0.5 to 2.0 prism diopters, that it did not trouble them.

Six patients had a marked hyperphoria. One case was of a woman whose eye had previously been unsuccessfully operated upon by the Gonin method. The hole was just under the superior rectus, so that it was necessary to cut it off on two occasions. There developed a troublesome hyperphoria of 12 prism diopters. As the patient was quite uncoöperative subsequent muscle surgery to correct this was not undertaken.

In the second case there had previously been a marked hyperphoria, for the patient was wearing 10 prism diopters of vertical prisms in her glasses before the operation. Subsequently a marked hyperphoria developed postoperatively (26 prism diopters of hyperphoria). A cinch shortening of the superior rectus of the opposite eye reduced this to 5 prism diopters, making the patient quite comfortable.

The third was in one of the patients

operated on twice. Here a hyperphoria of 6 prism diopters developed, but this receded to 3 prism diopters after a year. With this corrected by prisms the patient had single binocular vision and read comfortably.

The fourth patient had a two-stage operation with tenotomies of the inferior and, later, superior rectus. Before the operations she already had a hyperphoria of 6 prism diopters, for which she had been wearing prisms. Subsequently, she again was comfortable with prisms in spite of 7 prism diopters of hyperphoria.

The fifth patient had a hyperphoria of 4 prism diopters, but was absolutely comfortable. This, in spite of the fact that the operated-on eye had reasonably good vision (15/50).

Thus of the 16 cases with complete tenotomy of a vertical rectus, three needed prisms to be comfortable, one needed a muscle operation, and one, refusing both, was uncomfortable. In other words only one out of 16 was uncomfortable from hyperphoria.

There were four cases in two-eyed people operated upon without tenotomy. Of these one developed a hyperphoria of 2.5 prism diopters which, fortunately, did not trouble him. Another developed 7 prism diopters which also did not trouble him, probably because the eye had been amblyopic since birth.

A third patient developed a hyperphoria of 10 prism diopters after tenotomy of the external rectus. In spite of vision as good as in his unoperated-on eye, he had no complaints.

From the foregoing it can be seen that troublesome hyperphoria never develops as the result of a complete tenotomy of a vertical rectus (with muscle resutured to insertion), when only one operation is undertaken. A slight hyperphoria may develop without tenotomy, due to the

formation of scar tissue.

Of course in some cases a complete tenotomy of the internal or external rectus was performed. This might, and often did, result in some exophoria or esophoria. However, exophoria and esophoria are such frequent findings that their presence could not certainly be charged to a tenotomy. Furthermore, considerable exophoria or esophoria may be present, usually without subjective symptoms. Therefore the presence or absence of horizontal heterophoria has not been studied in this résumé.

Development of cataract: The lenses showed no abnormal development of cataract, with the following exceptions:

The first traumatic case has already been described as a traumatic cataract following a perforating injury with rupture of the lens capsule and iris prolapse. Here the lens became quite opaque, preventing a view of the fundus.

The second case was also traumatic, the eye having been struck by a flying piece of wood, with a blow severe enough to keep the patient from work for two weeks. A lens opacity developed slowly just under the posterior capsule, in the temporo-inferior quadrant. It had a typical "ground-glass" appearance, which is so characteristic of lens opacities developing after contusion of the eyeball. Vision has decreased slightly from 15/50 to 15/70.

The third case was in a boy, aged 16 years. The lens when examined with a slitlamp showed five or six striate opacities, placed almost like "riders" in the peripheral cortex of the temporal superior quadrant; they did not interfere with vision. These could very possibly be the result of the original contusion, which had been severe enough to cause a massive hyphema, and therefore may also be classed as a traumatic cataract.

In the fourth case there was a tremendous postoperative reaction, with marked iritis, hypopyon, edema, and so on. It was necessary to resort to intravenous typhoid vaccine injections to combat the uveitis. Whether this was an exogenous infection or a marked endogenous uveitis could not be determined. The eye finally quieted down but showed a typical complicated cataract, with posterior synechia. The development of this lens opacity was thus obviously not due to the diathermy current, but rather due to the cyclitis.

In the last case, a woman of 55 years was operated on twice. Diathermy had been confined to the temporal portion of the eye. Several months later the lens developed a peculiar opacity in the anterior and posterior nasal quadrants, outside of the pupillary area. The nuclei of both lenses were sclerotic and both lenses contained many fine senile opacities. While the operation very possibly caused this lenticular opacity in the cortex, this cannot be certified. The opacity has not increased in size in nine months.

As most of the other cases were in persons over 50, numerous lens opacities were found. These, however, were always similar to opacities found in the lens of the unoperated-on eye and were typical of senile changes as seen in other patients. Thus, except for the one case just described, in spite of the fact that in many cases the diathermy current had been applied as close to the limbus as 8 mm., no untoward effects attributable to the diathermy current were seen in the lens. One may therefore be assured that

the diathermy operation will not cause formation of cataract in the lens.

SUMMARY

Of the 63 patients who had been operated upon at least a year previously, 37, or 58 percent, had a successful issue. Of these 37 successful cases, only 32 could be found for reexamination.

All cases had been operated upon by the Safar method of multiple diathermy puncture. While in the earliest cases only one line of pins had been inserted, in all the later cases double rows of pins had been used, together with transcleral treatment (Larsson) or with bident electrode.

There were four cases of more than four years' standing, five of more than three years', six of more than two years', and eighteen of more than one year's standing.

No relapse had occurred in any case which was "cured" for three months.

Four patients "cured" had a recurrence within three months of the first operation, but were permanently cured by a second operation, while a fifth had two recurrences within the same period of time and was cured by a third operation.

Only one case of cataract developed in previously uninjured lenses.

Three cases of traumatic complicated cataract showed an increase in density of the lens opacity, as did one of complicated cataract.

All vision once regained was successfully retained except in three cases of cataract.

490 Post Street.

PAPILLITIS AND PAPILLEDEMA IN MULTIPLE SCLEROSIS*

SAUL SUGAR, M.D.

Chicago

The polymorphic manifestations of multiple sclerosis are not infrequently seen by the ophthalmologist, since ocular symptoms occur in about half of all cases of this disease at some time during its course. Cases with papillitis and papilledema, however, have been relatively few, especially in the recent literature. Marshall and Laird¹ in their recent review of 100 cases of multiple sclerosis mention four cases of blurring of disc margins or actual neuritis but no case of papilledema.

Review of the literature reveals 36 cases of multiple sclerosis in which definite papillitis or papilledema was described. Of these the majority were in females, as in the general group of cases of multiple sclerosis. The ages varied between 13 and 40 years.

Bruns and Stölting² in 1900 reported two cases of bilateral choked disc with diminished visual acuity and neurologic signs. Both cases were diagnosed as tumor cerebri. The disc elevation receded in both. The first patient had normal discs and vision 10 months later. The second came to autopsy and was proved to have had multiple sclerosis. Rosenfeld³ in 1903 reported a case with bilateral choked discs, diagnosed as tumor cerebri. Later neurological signs caused a change of the diagnosis to multiple sclerosis. This was proved on subsequent pathological examination.**

* From the Findlay Service, Illinois Eye and Ear Infirmary, Dr. Harry S. Gradle, director, and the Michael Reese Hospital, Department of Ophthalmology.

** Since writing this paper, the author has found three additional cases of unilateral papilledema, one of which was at first thought to be a case of frontal tumor, described by L. Paton (Papilledema in disseminated neuritis.

A total of 14 cases with bilateral choked disc have been reported by Tschirkowsky,⁴ Frank,⁵ Wilbrand-Saenger,⁶ Marburg,⁷ Oloff,⁸ Weil,⁹ Schaeffer,¹⁰ Fleischer,¹¹ de Montaud,¹² and Adler.¹³ Two cases of multiple sclerosis with unilateral choked disc were reported by Hillel¹⁴ and Tarle.¹⁵ Fleischer¹¹ has reported 12 cases of acute papillitis, six of which later developed multiple sclerosis. Four of the latter were bilateral.

Eleven cases described as having been of acute papillitis in multiple sclerosis were reported by Müller,¹⁶ Langenbeck,¹⁷ Wendenburg,¹⁸ Oppenheim,¹⁹ Kyrieleis,²⁰ Fox,²¹ Bollock,²² and Petry.²³

CASE REPORTS

Two cases of definite clinical multiple sclerosis with choked disc are presented:

Case 1. Mrs. M. N., a 39-year-old white female, presented herself on April 12, 1938, because of sudden loss of vision in the left eye one week previously. There had been no inflammation nor pain. Vision was 20/25 in the right eye, corrected with +0.75 D. sph. \approx +0.75 D. cyl. ax. 90°. With the left eye the patient was able to count fingers at two feet. Examination of the disc and fundus of the right eye revealed no abnormality. The disc of the left eye was elevated 2½ diopters, with several small hemorrhages on its upper part. The physiological cup was present, although the lamina cribrosa could not be seen. There was no involvement of the surrounding retina nor haziness of the vitreous. Vessels, macula, and periphery were normal. Visual-field examination of the right eye was entirely normal. The

Trans. Ophth. Soc. U. Kingdom, 1914, v. 34, p. 252).

left peripheral field was contracted concentrically to within 10 degrees of the fixation point, using a 5-mm. white target on the Ferree-Rand perimeter. A relative central scotoma for white, absolute for colors, was present at the fixation point only, using a 5 mm. target at one meter's distance. Tactile tensions were normal. Slitlamp examination revealed no evidences of inflammation in the anterior segments. Although the appearance of the disc was that of papilledema, a tentative diagnosis of optic neuritis of the left eye was made because of the visual disturbance. The patient could not enter the hospital immediately for etiological investigation so 10 c.c. of boiled milk was given intramuscularly.

Six days later the patient entered the hospital. At this time additional history was obtained of stiffness in the legs, especially in the morning, for the past three months, and dizziness for a year prior to the onset of the present visual difficulty. Vision in the left eye was now 20/200 uncorrected and corrected with +1.25 D. sph. \approx +0.25 D. cyl. ax. 90°. The disc was now elevated only 1½ diopters. The peripheral field was normal. The central scotoma remained unchanged, and the blind spot was slightly enlarged. Nystagmus was noted upon the patient's looking to the right side and on looking upward. Blood counts and urine examination were normal. The blood Wassermann reaction was negative. The Mantoux test was slightly positive. X-ray films of the teeth were negative. Clinical ear, nose, and throat examinations revealed no pathology. X-ray examination of the sinuses showed slight haziness of the right antrum. Physical examination revealed only neurological findings suggestive of multiple sclerosis. A corroborating neurological examination by Dr. C. Neymann revealed the following positive findings:

Horizontal nystagmus on looking to right and upward. The tongue on extension deviates slightly to the right. Absent abdominal reflexes. Both legs spastic with positive Babinski bilaterally. Abortive knee and ankle clonus. Exaggerated knee and ankle jerks. Slightly exaggerated right biceps reflex. Drooping shoulders. Spastic gait. Positive Romberg sign. X-ray films of the skull were negative. Spinal puncture: Wassermann, negative; Pandy and Ross-Jones, negative. No cells. Gold-sol curve 2332111111.

On April 22, 1938, 10 days after the first examination, vision in the left eye was 20/65. A small absolute central color scotoma was present. On April 26th the vision in each eye was 20/25 plus 2. There was no central scotoma. The disc of the left eye was flat, with slight blurring of the margin nasally; no temporal pallor.

The patient received two intravenous injections of 15 and 25 million killed typhoid bacilli, respectively, on April 19th and April 26th.

Case 2. W. T., a 28-year-old, single, white female, entered the hospital on June 6, 1933. She had been well until four weeks previously. After walking all day she suddenly became dizzy one night and began to have nonprojectile vomiting. She noticed that turning her head to the left or lying on the left side produced dizziness and at times retching and vomiting.

Tinnitus in the left ear had been present for one to two days at onset of the present illness but did not persist. This was followed by impaired hearing on the left side and a feeling of numbness about the left ear and left side of face. With the onset of impaired hearing, the patient noticed sudden blurring of vision. She was able to see motion but could not define objects even at close range.

At the onset of this difficulty the patient began to have weakness of the left arm and leg. The leg weakness improved after several days. Occasional paresthesias in the left arm and leg were pres-

ent. Occasionally the arm and leg began to shake spontaneously. At times, in grasping for objects, the patient could not control the direction of her hands.

Three weeks before admission the patient had had an episode of dizziness, nausea, and vomiting associated with a dull aching pain in the right lower quadrant. No fever was present. She was operated on for appendicitis with uneventful recovery. The symptoms, except the dull abdominal pain, remained unchanged.

The patient had had occasional transient suboccipital headache during the four weeks prior to admission.

Neurological examination on June 7, 1933, by Dr. T. Stone revealed the following positive findings:

The right palpebral fissure was wider than the left. Bilateral VIth nerve weakness, left greater than right. Occasional spontaneous lateral nystagmus and lateral nystagmus on fixation to the right and left, more so to left. There was apparent inability to raise the eyeballs upward. Pupils were dilated and reacted sluggishly to light, less sluggishly to accommodation. Left cheek and upper lip hyperesthetic. Defective left hearing. Left angle of mouth did not move so well as the right nor did it elevate so high as the right. Left hemiataxia. Wrist, triceps, biceps, supinator, knee, and ankle jerks were bilaterally present and slightly diminished. Abdominal reflexes were present, greater on the right than on the left. A diagnosis of posterior-fossa lesion suggestive of arachnoiditis or cerebellopontine angle tumor was made.

Hearing examination by Dr. S. Pearlman revealed left middle ear or conduction type of deafness.

Ophthalmoscopic examination was made on June 11th by Dr. Leo Mayer, with the following observations: *Right eye.* The media were clear. The disc was distinctly outlined with mild temporal pallor. The arteries were somewhat attenuated and the arterioles of the macular region tortuous. Otherwise the fundus was entirely normal. *Left eye.* The media were clear. The disc was distinct in outline, especially on the temporal side,

which was markedly pale. The central excavation showed more definitely than in the right eye but the lamina cribrosa was not seen. The arteries were similar to those of the right eye. Vision of the right eye was ability to count fingers at 6 inches; of the left eye, ability to count fingers at 12 inches.

Spinal-fluid examination: The fluid was clear; the pressure not increased. Pandy and Ross-Jones reactions were negative; 6 cells per cu. mm. Wassermann reaction was negative. Lange's gold-sol curve, 0000110000.

Blood Wassermann reaction was negative. RBC 4,200,000; hemoglobin 70 per cent; WBC 8,100; differential normal; blood sugar, 60; NPN 28. The urine showed a trace of albumin, with many white cells in clumps.

On June 20th cystoscopy revealed an acute generalized cystitis with loss of trabeculation in the bladder. The urinary function became normal on acidifying the urine and the instillation of 20-percent argyrol into the bladder.

X-ray studies of the skull revealed no evidence of pathology.

The patient was placed on quinine therapy and discharged on July 11, 1933, with a diagnosis of multiple sclerosis.

The patient was well at home except for dizzy sensations when resting on the left side until July 31, 1933, when she noticed a black cloud in front of her left eye. Within a few hours there was a complete loss of vision.

On readmission to the hospital on August 3d, the eye examination by Dr. M. L. Folk revealed that both pupils were dilated 7 to 8 mm., and did not react to light. No light perception was present in either eye. The right disc was elevated 4 diopters and markedly edematous. The veins were markedly distended and the arteries narrowed. The vessels were buried in the

edema and appeared interrupted in their course. The disc of the left eye appeared the same, elevated $2\frac{1}{2}$ diopters. There were a few small hemorrhages on the upper disc margin.

Two intravenous injections of 50-percent glucose solution were administered on the following day. From then until the 21st of August, six intravenous injections of typhoid vaccine, beginning with 15 million bacilli, were administered. These were gradually increased to 200 million bacilli in the last dose.

On August 29th the discs were flat and well outlined. Vision increased until, on September 6th, the patient was able to recognize large objects close by with each eye. Vision slowly increased to 20/65, corrected in each eye, and has remained the same to the present time. Both discs show secondary atrophy.

COMMENT

These cases are examples of the two different types recorded in the literature, the first type with unilateral choked disc and marked visual disturbance with rapid regression. Often the second eye becomes involved at a later date. The second and more frequent is the bilateral type, resembling cases of intracranial tumor. The ophthalmologist may assist greatly in the differential diagnosis of these cases.

In nearly all of the reported cases no record of the amount of disc elevation was made. Thus some difficulty may occur in distinguishing between some of the cases of papillitis and papilledema. In both cases reported here the appearance of the disc was that of choked disc with visual findings of optic neuritis. It is probable that in each the mild inflammatory signs were obscured by the signs of papilledema. In neither case was there any involvement of the surrounding retina nor filling of the physiological cup with inflammatory exudate extending into

the vitreous around the disc, as would be expected in a case of optic neuritis *per se*. This idea of mild inflammation superimposed by edema agrees with the histopathological findings reported in the literature.

Two views are held as to the nervous-tissue change in multiple sclerosis. Has-sin²⁴ believes it to be a degenerative process due to some unknown toxin, probably endogenous. Spiller²⁵ regards it as the result of a previous inflammatory change of an acute nature.

Holden²⁶ states that characteristic plaques may occur at any point in the optic nerves or tracts and involve the axial fiber bundles with great frequency. The inflammatory exudate that occurs at first merely compresses the optic-nerve fibers and interferes with their function. Later the medullary sheaths break down and glial proliferation occurs. The axis cylinders are not usually destroyed.

Rosenfeld,² in his cases, reported plaques in the chiasm and both optic nerves. The optic nerves were in places reduced to the size of the oculomotor nerve. Immediately behind the lamina cribrosa on each side were found foci in which the myelin sheaths of the nerve fibers were absent but most of the axis cylinders remained intact. The dural sheaths were in contact with the nerves in these areas.

Tschirkowsky,⁴ in histopathologic studies of his case, noted widening of the perivascular lymph spaces, infiltration of the tissue spaces with small granular cells, and glial proliferation.

From the foregoing one may conclude that a plaque immediately behind the lamina cribrosa causes the typical infiltration, dilatation of the perivascular lymph spaces, and involvement of the axial fibers. Swelling of the nerve in this area within the nonyielding dural sheath may cause venous compression and papilledema.

SUMMARY

Two cases of choked disc occurring in multiple sclerosis are presented together with a review of the literature.

In any case of choked disc with marked impairment of vision, multiple sclerosis should be considered in the differential diagnosis.

Recognition of the occurrence of this condition may help avoid unnecessary neurosurgical procedure.

I am indebted to Drs. Leo Mayer and Theodore Stone for permission to report the second case.

DYSOSTOSIS CRANIO-FACIALIS (CROUZON)

ARLINGTON C. KRAUSE, M.D.,* AND DOUGLAS N. BUCHANAN, M.D.*
Chicago

Innumerable cases of malformation of the head and face with associated ocular symptoms have been reported from the time of von Graefe in 1866. The least confusing of all the systems which have been recommended for these cranial deformities is the classification of Waardenburg.¹ He has classified high brachycephalic skulls into the acquired form, or hypsicephaly, and the true form, or acrocephaly. Under the hypsicephaly belong all the kinds of skulls that are more or less pointed during the course of cranial development by the effect of diseases with a definite etiology such as syphilis, meningitis, and rickets. Under acrocephaly are grouped acrocephalia anterior, media, and posterior. Although intermediate forms are known, acrocephalia media has four quite well-defined secondary groups; that is, (a) oxycephaly proper (often called tower head, ox-head or turriccephaly), (b) acrocephalo-syndactyly of Alpert, (c) hypertelorism of Greig, and (d) craniofacial dysostosis of Crouzon (sometimes called parrot head or Papageienschädel).

Dysostosis cranio-facialis is the name of a rare cranial deformity which has not been reported under this name in the United States. It is a disease typically characterized by exophthalmos, atrophy of the maxilla, prognathism of the mandible, and deformity around the sagittal suture and bregma. Cases of this disease may have been unknowingly taken as examples of oxycephaly because the history and examination of the patient as recorded in the literature are frequently

insufficient to place this disease in the subdivision of oxycephaly.

Etiology and pathology. Dysostosis cranio-facialis appears to be a primary developmental anomaly. There is no good reason to suppose that the disease is caused by rickets, syphilis, fetal meningitis, or osteitis. Ida Mann,² who has brought forth a theory based on ontogenetic and phylogenetic reasons, states:

The primary anomaly is undoubtedly failure of the lower part of the skull to expand. This places the defect primarily in the mesoderm, from which are formed the bones of the base and sides of the skull. If we now consider the results of this failure of mesoderm, ectoderm being unaffected, we should realize in the first instance that the rapidly widening brain growing at its normal rate will not be properly accommodated within the too narrow skull. This will lead to two things, firstly, expansion of the only normal portion of the skull, namely the vault, and secondly, raised intracranial tension (giving rise to convulsions, headaches, papilloedema, and consecutive optic atrophy). The shape of the skull and the condition of the eye are thus determined by the primary mesodermal failure in the region of the alisphenoids and temporals. The continuance of a high intracranial tension during the growth period will lead to a secondary thinning of the skull-bones (digital impressions). . . .

Symptoms and physical signs. The remarkable characteristics of dysostosis cranio-facialis may vary to any degree, from a scarcely recognizable deformity to the extreme deformation that is noted in the description of the case presented here. The end effect is apparently dependent upon the duration and rapidity of the development of the anomaly. The oxycephalic apical bulge of the cranial vault may take various shapes such as a small boss, dome, or even a crest. The peculiar facial distortion may be slight or marked.

The chief ocular symptoms are: exophthalmos, optic atrophy, strabismus, nys-

* From the Division of Ophthalmology, Department of Surgery, and the Department of Pediatrics, University of Chicago.

tagmus, and obliquity of the palpebral fissures. Exophthalmos may be noticeable from birth and may precede the cranial malformation. It is always extreme in craniofacial dysostosis because of intra-orbital venous congestion arising from the constriction of the orbital foramina and because of the shallowness of the orbital cavities. Luxation of the bulb may occur. Optic atrophy is caused by (a) intracranial hypertension, (b) mechanical traction resulting from the malformation of the base of the cranium and optic foramina which lengthens the optic canal, and (c) constriction of the optic foramina, especially transversely. Total blindness may occur from these effects. Strabismus is attributed to amblyopia resulting from optic atrophy, to muscular deficiency, and to malformation of the orbits. In cases with optic atrophy, nystagmus may be observed. The obliquity of the palpebral opening is contrary to that found in mongolism. If the lids are prevented from closing by the exophthalmos, corneal disease occurs.

The facial characteristics are: an arched nose with widening and depression of the nasal root, a prognathism of the lower maxillary, and an atrophy of the maxilla.

The cranial malformation results from the deformity of the sagittal suture and bregma and also from the intracranial hypertension giving rise to interdigital impressions of the skull.

The disease generally shows a familial and hereditary character.

Besides the typical form of this disease first recognized by Crouzon,³ there are cases in which the cranial defect is similar to oxycephaly. Vogt's⁴ case with syndactyly is a reminder of the disease described by Alpert.⁵ These intermediate forms suggest that the various subgroups of oxycephaly have a relatively similar origin. The Crouzon subgroup seems to show a

dominant heredity. Most of the cases that have been described are in the literature of the Latin countries and are patients of French stock.

Differential diagnosis. The diagnosis of dysostosis cranio-facialis may be easily confused with hypertelorism but not with oxycephaly proper or acrocephalo-syndactyly. The characteristics of hypertelorism are: large triangular orbits with a large angle of axial deviation, enlargement of the nasal bones, atrophy of the superior maxillary bone and foetal appearance of the lower maxillary with prognathism, prominent frontal protuberance, and lack of digital impressions of the skull.

Prognosis. The incomplete chronological history of these cases makes it difficult to predict the final outcome. Few deaths have occurred from intercurrent diseases. Several patients have reached old age. A low mentality indicates a poor prognosis.

Treatment. The malformation cannot be corrected by any known means. A decompression may serve to decrease the intracranial hypertension and operative procedures may release the pressure on the optic nerve. The condition of the eyes should be watched and appropriately treated by an ophthalmologist.

REPORT OF A CASE

R.P., a boy, aged 2½ years, American (figs. 1 and 2), was brought to the clinic for an examination. The mother believed that the child was not normal in appearance and was slow in development. The father and the other two children were living and well and were normal physically and mentally. The mother had frequent major convulsions. The father's brother had five children, one of whom had an absentminded appearance and was delayed in learning to talk, walk, and control his bowels. The patient was a full-term breech-delivered infant, weighing

Fig. 1 (Krause and Buchanan). A case of craniofacial dysostosis.

Fig. 2 (Krause and Buchanan). Same case, profile.

7.5 pounds (3.4 kg.). He fed himself at 12 months; walked at 17 months; used two to three words together and associated words with objects at 27 months. Bowel movements were trained but urina-

tion was uncontrolled. The child was breast fed for six weeks and then placed on a formula of cow's milk. At one year of age he had one convulsion. Shortly after this he had whooping cough and

Figs. 3 and 4 (Krause and Buchanan). X-ray studies of a case of craniofacial dysostosis.

measles. At 15 months his tonsils and adenoids were removed. There was no history of accident nor other operations. No signs of syphilis were found.

Examination. The patient was a well-nourished child with queer appearance. The occipito-frontal circumference was 49 cm. The anterior fontanelle bulged upward. The palpebral openings slanted down and inwards about 15 degrees. These openings were 3 mm. wide when the child was asleep. The moderate ptosis of the upper lids resulted in a wrinkled brow. The widely set eyes were parallel. In sleep they diverged markedly. As measured on the Hertel exophthalmometer, the right eye was 27 and the left eye 26 mm. when the instrument was set at 99 mm. The external ocular movements were normal. The corneae were clear and were 12 mm. in diameter. The anterior chambers were of normal depth. The iris patterns were well made out. The pupils reacted to light and during accommodation. The tactile tension was normal. The re-

fractive media were clear. The fundus examination showed that the disc margins were blurred and the vessels were markedly arched over the pale papilla. No macular lesions were seen. The short pointed nose appeared excessively broad at the root. The mouth was constantly held open and the tongue slightly protruded. The breathing was stertorous and accompanied by drooling of the saliva. The palate was highly arched. The chest was pigeon breasted. Over the coccyx a pilonidal cyst was found.

Laboratory data. Urine, blood count, and spinal fluid were normal. The blood and spinal-fluid Wassermann tests were negative. The roentgen examination (figs. 3 and 4) showed that the vault of the skull was extremely thin and the sutures were closed. Digital impressions were prominent. The area about the anterior fontanelle protruded outwardly. A diploic channel was seen. Sphenoidal ridges and orbits were normal. Marked absorption was found about the roots of the teeth.

The mandible gave the appearance of prognathism because the bones of the face around the nose were incompletely developed. The sella turcica was large. The posterior clinoid was enlarged. The bones of the left hand and forearm showed decreased density of the cortex and an increase of the trabeculation.

A diagnosis was made of craniofacial dysostosis, hydrocephalus, bilateral exophthalmos, papilledema, and secondary optic atrophy.

Subsequent history. The child was sent home and 48 days later was admitted to the hospital. An osteoplastic frontal exploration of the skull and decompression of the right orbit and right subtemporal region were performed on the second day in the hospital. A week after the operation the conjunctiva of the right eye was moderately injected. The weakness of the winking reflex of the right eye and the tendency to keep the eye open resulted in a small superficial corneal opacity. Four weeks after the operation the condition of the left eye was unchanged. The exophthalmometer reading was: right, 33

mm., left 26 mm. at 98 mm. The examination of the right eye showed that it diverged about 45 degrees and possessed no power of convergence. The pupil of the right eye was 7.5 mm. in diameter, and of the left, 5.5 mm. The pupil of the right eye gave no direct reaction to light. The interpupillary opening of this eye was 15 mm. wide when the child was sleeping and 16 mm. wide when awake or 5 mm. wider than that of the left. A mild conjunctivitis persisted in spite of constant treatment, and the central corneal epithelium tended to become eroded.

SUMMARY

Reported in this article is a case of dysostosis cranio-facialis or Crouzon's disease with typical symptoms and confirmed by roentgen-ray examination. There is no apparent record of this disease in the American literature. In spite of operative decompression of the cranium and right orbit there is no reason to believe the prognosis will be favorable for either the eye, mentality, or life.

LECTURES ON MOTOR ANOMALIES*

VI. PRINCIPLES OF SURGICAL TREATMENT

A. BIELSCHOWSKY, M.D.

Hanover, New Hampshire

Divergent squint has a much better prospect with regard to treatment. There are several reasons for this. First, it occurs very seldom in earliest childhood. Most of the patients have passed their sixth year, so that the development of the fusion apparatus is complete when the divergent squint appears. In a relatively high percentage of the cases the squint remains periodic if the fusion tendency is able to overcome the anomalous position of rest by the convergence innervation. Cases of divergent squint have the advantage that the compensating convergence innervation is dependent on the will and has a larger amplitude than all the other fusion innervations. Therefore, convergence exercises will produce a better result than will the divergence exercises required in convergent strabismus. Further, in divergent squint the risk of getting an overcorrection by the proper operative procedure is relatively small, whereas in convergent squint this danger must always be considered, particularly in early childhood. As was said before, the change of the topographic anatomic conditions within the orbits in growing children favors the tendency to divergence, and may reduce a convergent squint or cause it to disappear spontaneously. I never saw a spontaneous diminution of permanent divergent squint, but very often the contrary—that is, a gradual increase of the divergence—while a periodic squint which the patient can overcome voluntarily may become manifest

less frequently if a delicate child gradually becomes stronger or an existing aniseikonia, which may interfere with fusion, has been corrected. But the divergent position of rest will always remain the same, or will even be found to have increased as compared with the divergence determined previously. The visual act, with regard to the relations between the two retinae, is very interesting, particularly in cases in which the divergence is temporarily latent. While perfect binocular vision with depth perception and fusional amplitude might be found during the latent period, not only will diplopia be absent during the periods of manifest squint, due to suppression of the images of the squinting eye, but if double images are produced by one of the aforementioned methods they will not be crossed but show a behavior pointing to an anomalous retinal correspondence adapted approximately to the divergent position of the eyes. A strong prism, base in, for instance, will produce homonymous double images with the same separation as in cases of orthophoria, or if a vertical prism is used the double images will be seen one above the other without, or with a very slight, lateral displacement. In the afterimage test the two images will not form a cross, but the afterimages belonging to the right eye will be seen, as a rule, displaced more or less to the right of the center of the left afterimage. Such patients make alternate use of the normal and the anomalous mode of localization, according as to whether the divergence is kept latent by the compensating innervation or is manifest. In most cases of permanent di-

* From The Dartmouth Eye Institute, Dartmouth Medical School. Read before the Seventh Annual Mid-Winter Clinical Course of the Research Study Club, Los Angeles, California, January, 1938.

vergent squint an anomalous correspondence will be found, but in these cases there also prevails an alternating uniocular vision with strong suppression of the retinal images of the squinting eye. Here the phenomenon of horror fusionis occurs even more frequently than it does in convergent squint and must be looked for in every case of alternating divergent squint. After the angle of squint has been reduced by operation, the patient will have a more or less disturbing homonymous diplopia, either transient, if the abnormal correspondence is superseded by the normal one, or persisting in some cases for a longer period until suppression of the retinal images of the squinting eye returns or binocular single vision is restored. Since divergent strabismus, in most cases, is based on anatomico-mechanical conditions, refractive errors not playing any important part in the etiology, the patient cannot derive much profit from glasses, apart from the equalization of the vision by the correction of a possible anisometropia or aniseikonia, and facilitation of binocular fixation of near objects by the correction of any myopia. In cases of hyperopia, correcting glasses may, indeed, increase the divergence but, of course, one would not deprive such people of the comfort of correcting glasses on account of the unimportant increase of the angle of squint. As to the question of the age at which children with divergent squint can be operated on, one must consider the fact that divergence frequently increases during the growing period so that a good result obtained by an operation in early childhood will be gradually diminished. I have seen patients with divergent squint that had been removed completely by operation when they were six years old; six years later the same amount of squint had returned and they had to undergo another operation. Therefore, I prefer to operate on children with divergent squint not

prior to the twelfth year, if the permanent squint is not of a very high degree and both eyes have equally good vision. In the meantime fusion exercises may be given to all patients capable of overcoming the deviation temporarily. In a permanent squint these exercises are of no use.

Permanent *vertical* squint of a purely concomitant type is a very rare affection. In the great majority of cases the hyperphoria becomes manifest temporarily, inducing the patient to consult the doctor on account of the diplopia or the disfigurement. Considering the various types of vertical deviations discussed previously, a very careful examination is indispensable in order to find out to which of the different groups the individual case belongs. One will recognize the deviation as belonging to the concomitant type only if there are no signs and symptoms of a paretic origin or of the so-called overfunction of the inferior oblique muscles. This may be easily ascertained by examining the double images in the whole field of fixation with the red glass successively before the right and left eye. If there is neither a definite increase, respectively decrease of the vertical deviations, nor a conclination, respectively disclination of the corresponding retinal meridians in any part of the field of fixation, a concomitant hyperphoria may be taken for granted. Spontaneous diplopia is frequently absent, or will be noticed only occasionally if the fusion tendency is strong enough to overcome the anomalous position of the eyes temporarily. In the latter case subjective troubles, such as eyestrain, headaches, and other conditions, may occur. They are due to the effort to produce and maintain the compensating vertical deviation innervation. As to the amount of hyperphoria or periodic hypertropia which may cause these troubles, there is no regularity. I know patients with a high amount of vertical deviation who have no subjective trou-

bles, and others who had suffered very much in spite of the insignificance of the deviation. The difference in reaction is due to differences in the general, particularly the nervous, condition. Suppression and anomalous retinal correspondence develop, as a rule, in the rare cases of a permanent, protracted vertical squint. Very frequently a vertical deviation of the concomitant type is combined with convergent and divergent squint. In cases in which, according to an anomalous correspondence, the afterimages show a vertical in addition to the lateral displacement, both components may coincide approximately with the objective angle of squint. Spontaneous decrease or disappearance of vertical deviations of a non-paretic type does not occur, so that operative procedures may be considered at any time provided that the deviation exceeds 5 (arc) degrees. Smaller deviations may require prisms that remove the subjective troubles in most cases.

True concomitant cyclotropias of such an amount as to require attention occur very seldom, whereas meridional declinations of paretic origin play an important part in the diagnosis and therapy of ocular paralyses.

As to the operative procedures in the various types of squint, I am not going to discuss the various operations on the muscles of the eye. But I should like to say a few words about my guiding principles for operations for strengthening and weakening the eye muscles. Strengthening can be effected either by an advancement or by a shortening operation. Personally, I prefer a combination of advancement with resection of a larger or smaller portion of the tendon according to the amount and the degree of deviation. In no case is it certain how many degrees of deviation will be corrected definitely by an advancement or shortening operation. The results obtained by identical operations in similar cases differ

within wide limits. Claude Worth, though admitting that it is impossible to estimate beforehand the results that will be obtained by operation, has maintained, in his well-known monograph on squint, that the immediate effect of his advancement operation is also the permanent result and that, therefore, no overcorrection is necessary. On this point I do not agree with Worth. The immediate effect of advancement, as well as of every shortening method, diminishes in the course of time, and I have always been satisfied if I obtained a considerable overcorrection as an immediate result of operation.

In my opinion it is wrong to refuse, as a matter of principle, to perform the muscle-weakening operations. The contrary opinion is based on the assertion that the effect of such operations is always incalculable and always produces a form of paralysis of the weakened muscle. Reference is made, further, to the disfigurement due to the postoperative exophthalmos and the recession of the caruncle. Indeed, these considerations are true enough for a simple tenotomy, but not for a recession operation safeguarded by a suture by which the separated tendon is prevented from receding farther than is desirable. Only in certain cases is it necessary to insert the suture into the sclera. I prefer, as a rule, to pass one needle of the double-armed suture through the tendon before I cut it, and then through the peripheral edge of the divided conjunctiva; the other needle is passed through the conjunctiva near the corneal margin. Then I make a loose loop of the ligature, which can be tightened or loosened still further, or removed on the following day, according to circumstances. I am thus able to modify the result to a certain degree, in any case preventing an undesirable overcorrection and cosmetic disfigurement. To the advocates of advancement and shortening operations, one might say that if the cor-

rection of a deviation is to be obtained in every case and solely by these operations, disadvantages almost as unwelcome as those that are imputed to the weakening operations must often be anticipated. The enophthalmos resulting from an excessive advancement, being always associated with the narrowing of the palpebral fissure, causes a cosmetic disfigurement as unsightly as the exophthalmos and the receding of the caruncle following an unguarded tenotomy. Moreover, excessive advancement of a muscle will restrict the function of its antagonist as much as an unguarded tenotomy of the latter.

In the vast majority of cases of convergent squint the inward movement is increased considerably without a corresponding diminution of the outward movement taking place. I do not see any reason for rejecting a recession of one or both of the internal recti in order to weaken their excessive functioning. Of course, one must take care through safeguarding sutures, that the weakened muscle retains a normal function. I have never seen a secondary divergent squint develop after a safeguarded recession in any of my cases of convergent squint, most of which I was able to follow up for several years after the operation. In cases of alternating squint I prefer to divide the operative effect between both eyes. There must be, as a rule, an interval of at least one month between the first and second operations, or better still, of several months, so that one may judge the definite result of the single operation. Always bearing in mind the highest principle of the physician—“*nil nocere*”—one should never be misled in the face of a seemingly inadequate effect of the recession, into increasing it at the risk of an excessive weakening of the muscle, except in cases of high amblyopia of the squinting eye, if there are reasons for leaving the other eye untouched. If the

result of a properly regulated recession of both the internal muscles is insufficient, an advancement or shortening of the external recti must be considered. In unilateral strabismus with monocular amblyopia and a high degree of squint, one would better operate on this eye in order to avoid an habitual turning of the head, which may occur after the internal rectus of the fixating eye has been weakened or the external rectus shortened or advanced. If the angle of squint is more than 20 degrees a recession of the internal rectus has to be combined with an advancement or shortening of the external rectus because an exaggerated recession as well as advancement may cause a disfiguring monocular exophthalmos or enophthalmos. In adults the risk of obtaining an overeffect—that is, a secondary divergence—by an adequate operation, is relatively small.

One should not aim, in any case of convergent squint, to achieve parallelism of the visual lines as an immediate result of the operation, since one would run the risk of a gradually developing secondary divergence. A small deviation of about 5 degrees of convergence must be left, particularly if the patients are very young children, since a spontaneous decrease of the convergence has to be taken into account. If the restoration of binocular single vision is obtainable at all, the fusion tendency would easily overcome the small amount of squint that has remained. If the inward movement of the eyes is not increased, one must advise against a weakening of the internal recti. Of the operations aiming at strengthening of the external recti, the O'Connor cinch operation may be preferable, particularly in cases of young children with a small angle of squint, because it can be better graded than the other shortening and advancing methods.

In divergent strabismus, the inward movement of the eyes is, as a rule, re-

stricted, without a perceptible increase of the outward movement. Excessive abduction will be found only exceptionally in cases of an extremely high deviation. Therefore the operative procedures must aim, first of all, at the strengthening of the weak internal recti muscles. If the angle of squint amounts to 20 degrees or more, an advancement and a shortening of both internal recti may be performed simultaneously, combined, if necessary, with a temporary severing of one or both the tendons of the external recti, with securing sutures to prevent receding. An ordinary recession of the external recti has, as a rule, no lasting effect, and if no excessive function of the external rectus exists, involves the risk of producing a parietic condition so that, apart from not achieving a sufficient reduction of the divergence in the primary position of the eyes, homonymous diplopia may occur when looking toward the side on which the weakened muscle has to act. Considering the fact that the immediate effect obtained by an advancement or shortening operation will decrease gradually, one must endeavor to obtain an overcorrection—that is, a certain amount of convergence—as the immediate result of one of these operations. There is no danger that the overeffect would remain permanently if it is to be obtained solely by strengthening the internal recti. The greater the original divergence may be, the greater ought to be the convergence produced as the immediate result of the strengthening operation. For instance, if the divergence were 20 degrees, an overcorrection up to 10 degrees would give approximate parallelism after the sutures had been removed. If a recession of one or both external recti were to be combined with the advancement or shortening of the internal recti, no overeffect, or at most a very small one, must be the goal.

There are cases of divergent strabis-

mus, fortunately rare, which baffle the doctor in spite of the greatest care and experience as to indication, and the greatest skill as to operative technique. I remember some such cases. One of them was of a five-year-old boy with a divergence of 30 degrees, a moderate hyperopia, and two-thirds vision in each eye; adduction was somewhat deficient, abduction not increased. After advancement of both internal recti, combined with recession of both external recti, there still remained a divergence of 20 degrees. Three years later advancement of both internal recti was repeated, both eyes being kept bandaged for eight days. The divergence was reduced to 12 degrees, which increased to 26 degrees within the next month. As adduction was still deficient, the internal recti were again advanced and shortened. In addition to the ordinary sutures, auxiliary double-armed needles were passed through the body of the muscles and fastened beyond the vertical meridian both above and below. The stitches all held and the immediate effect was all that could be desired, but divergence developed again gradually and increased to 30 degrees within three months. Assuming that this quite unusual behavior was due to a congenital anomaly, perhaps elastic bands which gave way for a while to the stronger action of the advanced and shortened muscles but which later overcame their resistance, I searched in vain for such a condition during the last operation. The etiology could not be cleared up apart from the statement, which seemed to support our supposition of a congenital anatomic anomaly, that the patient's brother was idiotic and had a convergent strabismus and congenital cataract.

That the best possible cosmetic result can be spoiled by the lack of fusion power, causing diplopia after the deviation had been removed, proves true also

in cases of divergent squint. A very important hindrance to the cure is sometimes produced by a neuropathic condition. Even if there is no true horror fusionis, the patient being able to fuse stereoscopic pictures, the fusional amplitude is nil, so that a residue of 1 or 2 degrees of the previous deviation produces intolerable diplopia, headaches, and so forth. In some of my cases of this type an antineuralgic medicament removing the headache caused the diplopia to disappear for several months. This and similar observations cannot be explained but by the assumption that in such cases both headaches and diplopia are symptoms of the same neurological process, or else the patient's general resistance may be so affected by the headaches that there is no longer sufficient energy to produce and maintain the adequate innervations of the oculomotor apparatus. That in such cases with a weak fusion faculty dissociated vertical-divergence innervations not infrequently also cause trouble and render the restoration of binocular single vision more difficult will be discussed later. Finally, there are cases in which divergence is not based on an anomalous position of rest, but is caused by an excessive divergence innervation, which will be discussed together with the other deviations of spastic origin.

Operative procedures in cases of true concomitant *vertical* deviations which do not show perceptible changes in the different parts of the field of fixation, are not frequent. They have to be considered in cases in which the squint amounts to more than 5 degrees. If, due to a monocular amblyopia, only the cosmetic disfigurement must be removed, one will retroplace the superior or inferior rectus of the weak eye as the case may require. If both eyes have fairly equal vision so that it is possible to obtain binocular single vision, one should operate on the eye that is deviated upward relative to

the other, considering that a slight restriction of the upward movement is not so important as a restriction of the downward movement of the eye operated upon. The eyes are used in the elevated position only rarely, so that a slight inequality of the upward movement, due to a possible postoperative insufficiency of one superior rectus, will hardly cause trouble, there being all the more reason not to, because when looking up the head is always moved in the same direction, whereby the eye movement is reduced to a minimum. Insufficiency of one of the depressor muscles, is, on the contrary, as a rule very annoying, since the eyes work mostly in a more or less lowered position and a compensatory habitual lowering of the head causes discomfort. Whether or not the superior rectus shall be weakened by a recession, or the inferior rectus strengthened in order to correct an upward deviation, will depend on the extension of the field of fixation. If it is considerably enlarged in the upper half without being narrowed correspondingly in the lower half, the superior rectus may be retroplaced with a safeguarding suture permitting a regulation of the effect, if necessary, the day after the operation. If the enlargement of the upper half and the restriction of the lower half of the field of fixation are approximately balanced, it is to a certain degree irrelevant which of the aforementioned operative procedures is selected.

The recession of the superior rectus can be graduated and regulated more easily than most of the advancement and shortening methods which may be considered for the strengthening of the function of the inferior rectus. I should think that of those methods the O'Connor cinch operation would permit the best subsequent regulation of the effect. Besides, this method would prevent a meridional declination (torsion) which might possibly produce an annoying

diplopia. The sensitivity to torsional deviation varies in the individual patients. However, as the rotating component of the vertical recti muscles is much weaker than that of the oblique muscles, a carefully safeguarded recession of the superior rectus does not, as a rule, cause any trouble. At any rate, in all cases in which vertical deviations are to be corrected by operation one must consider individual peculiarities, which may be difficult, if not impossible, to know beforehand. Such peculiarities may be illustrated by the following examples.

A man, 36 years of age, had been suffering with headaches and unsteady vision, especially in the street. He noticed diplopia occasionally after fatigue. Prisms gave relief only at times. When binocular vision was prevented, there was a deviation of the right eye downward; that is, a negative vertical deviation, gradually increasing to 9 degrees. Upon changing the visual direction, the negative vertical deviation varied a little, but the differences were slight and not constant for the same direction. Both eyes had vision of $\frac{6}{4}$ with $+1.0$. As the patient had previously worn prisms without any effect, I made a recession of the left superior rectus; the immediate result was an overeffect; namely, 10 degrees plus vertical deviation. By tying the safeguarding sutures, which were removed after four days, the plus vertical deviation was reduced to 1 to 2 degrees. But the sixth day it had increased to 8 degrees and the diplopia was very annoying. On the tenth day there were 9 degrees plus vertical deviation and 10 degrees convergence. The only thing that could be done was to advance the left superior rectus. Result: slight negative vertical deviation which had disappeared a week later. The patient felt very comfortable. A few days later he reported that upon awakening he noticed diplopia, which disappeared again, but he felt as

though his head were being compressed. Upon examination a negative vertical deviation was found, which increased to 7 degrees. After a month's vacation he reported that he felt decidedly better; he noticed diplopia only momentarily upon awakening. Examination showed scarcely one-half degree plus vertical deviation. During the next three months a latent plus vertical deviation of one-half to 2 degrees was always present. The patient complained only of occasional diplopia. The last examination showed $1\frac{1}{2}$ degrees negative vertical deviation, and convergence 4 to 5 degrees. Stereoscopic exercises for two weeks caused the diplopia to disappear. Headaches occurred only after prolonged reading. The neuropathic character of the ailment was evident from the way in which the patient, a strong, healthy-looking man, described it. He spoke now of a feeling of compression, then of a feeling of sand in the eyes, again of a blind feeling, a dazed state, as though he had been drinking too much, then again as if the brain were too loose, and so on. The course of the treatment also allowed drawing the conclusion that the vertical divergence was greatly influenced, if not directly caused, by abnormal innervations which could not be anticipated from the outset in the face of a fairly constant deviation pointing to an anomalous position of rest as the main, if not the only cause of the vertical divergence.

After an ordinary strabismus operation, it is usual for the tendon to be so well fixed five days after the operation that the safeguarding suture can be removed without fear of any appreciable change in the position of the eyes. Here the plus vertical deviation increased from 1 or 2 degrees to 9 degrees and a convergence appeared that had not been observed before. Still more strange was the appearance of an operative overeffect of 7 degrees 11 days after the advancement

had brought about balance, whereas usually the effect of an advancement operation gradually decreases during the first and second week after the operation. The overeffect in my patient's case also disappeared finally and was not noticed during the next five months.

In such cases, we are dealing with a fusion power of varying strength, depending upon the existing physical and psychic condition. To this is added abnormal stimulation of the vertical deviation centers, the origin of which is understood no more than that of other neuroses.

Another patient, 27 years of age, with an inherited neuropathic constitution, complained of eyestrain, headache, dizziness. The trouble had increased gradually to such a degree that he was unable to work and was very much worried about his future. A careful examination showed a right hyperphoria with all the characteristics of a typical concomitant deviation. A very strong fusion power kept the right hyperphoria of 15 (arc) degrees almost continually latent and it took a long time to manifest it by relaxation of the compensating negative vertical deviation innervation. A recession of the right superior rectus produced a good effect which, however, gradually disappeared, so that a right hyperphoria of almost 15 degrees still remained. Since there was also a slight meridional disclination, I decided to make a retroplacement of the left inferior rectus in order to restore the parallelism of the corresponding meridians. Again, the immediate result was satisfactory since the right hyperphoria was reduced to zero, but after five days the patient showed a *left* hyperphoria of 12 degrees, nearly the same degree to which the original opposite deviation had amounted. I could not understand what had caused this undesired overeffect, since I had taken all the necessary precautionary measures,

and it could indeed be proved that neither a wrong indication nor a faulty operative technique was to blame. There existed not a minimum of negative vertical deviation (*left* hyperphoria) during a bilateral occlusion of the eyes for a whole week; sometimes there was present even a small fraction of the original plus vertical deviation. Further, it was ascertained during a long period of observation, that when one eye was occluded or the fusion broken by a dark-red glass, at first the *left* hyperphoria became manifest and increased gradually, but after a while it decreased to zero. I cannot discuss in greater detail all the very interesting phenomena which I was able to control during a period of eight years. They are to be found in my article on the operative treatment of vertical deviations in Graefe's Archiv, 1921. Finally, the diplopia disappeared and the patient was happy and able to work. To explain the quite unusual behavior of the vertical deviation and the unexpected reaction to the operative procedure, one must take into account that, to overcome the high amount of the primary right hyperphoria a permanent excessive negative vertical deviation innervation was required and maintained by the very strong fusion power. It would seem therefore, that due to the long-standing excessive innervation an abnormal excitability of the negative vertical deviation center had *remained*, notwithstanding that it was no longer wanted after the operative correction of the positive vertical deviation. Though absent while both eyes were bandaged, this abnormal vertical deviation innervation arose as soon as the eyes were opened and the patient looked about. Whether this hypothesis is right or wrong I do not know, but I cannot think of a better one. In the first place, the neuropathic constitution was, of course, responsible for the peculiar fluctuations of the vertical deviation. The

good ultimate result supports the assumption of the nervous basis.

The vertical deviation is frequently combined with a convergent or divergent strabismus. Whether, in such cases, the lateral or the vertical deviation must be considered as the primary anomaly will not be discussed at present. If, after the removal of the greater deviation component, the fusion apparatus were not able to overcome the smaller component, a second operation would have to deal with it. In some of these cases

one may succeed in the attempt to remove both the lateral and the smaller vertical deviation by one operation. This may be attained if the lateral rectus muscles are not only advanced or retro-placed in the direction of their course—that is, in the horizontal direction—but are at the same time displaced above or below the horizontal meridian according as to whether an improvement in the function of the elevator or of the depressor muscles is desirable.

SOME PHYSIOLOGICAL AND ANATOMICAL ASPECTS OF THE CORNEA AFFECTING ITS PATHOLOGY*

THEODORE L. TERRY, M.D.

Boston

The cornea is relatively immune to the ravages of certain diffuse diseases such as early secondary syphilis, probably due to its simplicity and especially its lack of vascularity. On the other hand, it may be more liable to invasion by other disease processes. Lack of vascularity favors "sluggish, chronic, and somewhat intractable" pathological processes.¹ The cornea shares general bodily immunity only to a slight degree² and weak general bodily immunity can be acquired through corneal inoculation.³ The number of different pathological processes to be found in the cornea are limited, but variation in location and combination of these lesions give rise to the surprisingly large number of variants in the appearance of corneal diseases. Changes too minute to be observed in the skin would be more obvious in the transparent cornea.¹ Biomicroscopy has given much information concerning the pathological processes, yet the correlation of changes seen by means of the corneal microscope with known pathological

processes is far from complete, the exact pathology of many of the corneal diseases not being known.

A plea has been made for standardization of abbreviations used on ophthalmological records.⁴ Abbreviations for the anatomical structures of the cornea are also useful. The layers can be indicated by letters in alphabetic order, as follows:

- A Anterior epithelium
- B Bowman's membrane
- C Corpuscular layer (substantia propria)
- D Descemet's membrane
- E Endothelium (so-called)**

The epithelium of the cornea in the healthy state is relatively impervious to water, certain drugs, vital stains, and most bacterial toxins (toxins from gonococcus and corynebacterium, diphtheria excepted¹). For purposes of metabolism the epithelium passes oxygen into the cornea⁵ and carbon dioxide out.⁶ In fact, the term respiration is applied to this process.⁷

The mesenchymal epithelium or the so-

*From the Massachusetts Eye and Ear Infirmary, Harvard Medical School. Read before the New England Ophthalmological Society, March 15, 1938.

**No suggestion to change the names of the corneal layers is intended.

called endothelium of the cornea allows the passage of toxins in each direction. Toxic iritis often results from ulcerative keratitis, and ring abscess of the cornea may at times result from virulent endophthalmitis. The endothelium is also permeated by certain drugs. However, in its healthy state the endothelium, like the epithelium, is relatively impervious to water. Should either epithelium or endothelium be injured, water passes freely, giving rise to swelling of the substantia propria due to its turgescence and to edema of the cornea with subepithelial-vesicle formation.

The cells of the epithelium are bound together firmly not only by the intercellular cement substance and by protoplasmic continuity but also by the so-called tonofibers.⁸ No doubt, the interepithelial nerve fibers also support the epithelium as well as prevent side slipping of the layer. The cells appear to be bound to each other more firmly than they are bound to Bowman's membrane, since spaces between the cells are much less common than spaces between the cell layer and Bowman's membrane in edema of the cornea.

The temperature of the cornea is relatively low, the difference between cornea and iris temperature in the rabbit even reaching 5°C.⁹ The cornea can survive a temperature of -2°C. for 10 days.¹⁰ The lack of activity and the lower temperature of the cornea indicate that a very small amount of nutrition and oxygen must be required by the cornea normally. The nutrition can be derived from the limbus vessels, the aqueous, and the tears. In a healthy eye, the transparency of the cornea is not affected by filling the anterior chamber with air, thereby removing all contact with aqueous.¹¹ It is obvious, therefore, that the cornea can get sufficient nutrition from the tears and limbus vessels. The cornea does not suffer from lack of nutrition following a complete

peritomy,¹² following section of three fifths the corneal circumference,¹³ or following complete corneal grafts.¹⁴ It appears, then, that the cornea can get sufficient nutrition from the aqueous and the tears. The chemical analysis of tears indicates that sufficient protein, carbohydrate, and fat are present to be of nutritional value.

TABLE 1
NUTRIENT MATERIAL IN AQUEOUS AND TEARS¹⁵

	Protein	Quantities gram % Carbohy- drate	Fat
Aqueous Duke-Elder	.0269	.0983	.004
Tears	Ridley- Brown .669	Ridley- Brown .65	Mucus and Fat Fiericks .30

Epithelium at times may grow over necrotic corneal tissue or over fibrin and exudate. Nutrition for this epithelium seems to be from tears. Nutrition for growth of filaments in true filamentary keratitis seems to be from the tears also, although tears are scanty in true filamentary keratitis.¹⁶ Finally, absence of tears results in disturbances of the cornea of a type somewhat specific and different from drying alone.^{16, 17} The tears alone cannot furnish corneal nutrition. Wagenmann¹⁸ has shown that the cornea degenerates following loss of nutrition from the aqueous and the limbus vessels after the long ciliary arteries and most of the short ciliary arteries have been cut off. In stagnation of the aqueous, as met in long-standing glaucoma and chronic uveitis, nutritional disturbance of the cornea gives rise to degenerative pannus formation. Accumulation of toxins in the stagnant aqueous alone may account for the change, but sclerosis of vessels at the limbus may be a contributing factor.

The importance of nerve supply for

maintenance of a normal corneal condition is evidenced by the occurrence of neuro-paralytic keratitis following Gasserian-ganglion surgery. At the present time, this is explained most satisfactorily by loss of antidromic nerve impulses.¹⁹

CONCLUSIONS

1. It is suggested that the letters A, B, C, D, and E be used as standard abbreviations for the anterior corneal epithelium, Bowman's membrane, substantia propria

(corpuscular layer), Descemet's membrane, and so-called endothelium of the cornea.

2. The interepithelial nerve fibers tend to bind the epithelial cells together.

3. The cornea may derive some nutrition from tears as well as from limbus vessels and the aqueous.

4. Stagnation of aqueous is present and is probably an important factor in the production of the degenerative pannus.

MONOCULAR PROTECTION VERSUS MONOCULAR OCCLUSION

WILLIAM H. HOWARD, M.D.

Chicago

In the past year, several patients under my care have worn tinted transparent eyeshields. These patients may be divided into two groups: The first group consisted of one patient with laceration of the bulbar conjunctiva of the right eye, another with caterpillar keratitis, and the remainder were patients in which an imbedded foreign body had been removed from the cornea. In these cases satisfac-

Fig. 1 (Howard). Eyeshield with closed slit on each side.

tion was consistently reported. A second group consisted of patients who had either moderate or excessive tearing. One of these had a deep burn of the outer lower palpebral conjunctiva caused by hot metal. The others had acute catarrhal conjunctivitis. In this group the accumulation of moisture on the shield interfered with vision and presented a special problem, which will be discussed later. The final reports in both groups were in favorable contrast to the comments of patients who wore the complete-occlusion type of eyeshield.

In the new eyeshields that have been made a transparent green-colored material called Fibestos¹ is used. This is a

slow-burning material of the celluloid group. (I am given to understand that a noninflammable material will soon be marketed.) The shield² (fig. 1) has a small slit on each side. Other forms of construction will be tried.

PRINCIPLES OF THE NEW EYESHIELD

The ideal eye shield should possess the following characteristics: 1. It should be transparent; it may be clear or tinted depending upon its use. 2. The center-piece should be regular in curvature and be made of a relatively uniform refractive medium. 3. Its front piece should be convex in order to be free of the lids and the eyelashes and to allow for a moderate amount of cotton to be placed within when necessary. 4. It should be designed to fit the contour of the average orbit. 5. It should be made with two ties for proper fitting and adjusting. Note: a frequent cause of blepharospasm is the irritation to the eye lashes or lid margins due to improper adjustment of the eyeshield. 6. It should be aseptic and protected against contamination. 7. It should be light in weight. 8. It should be noninflammable. 9. It should be inexpensive.

When properly used, certain advantages are noted in this type of shield over the complete-occlusion type. With vision in both eyes instead of in only one, the patient is less incapacitated for both work and play. There is less nervous tension in the covered eye as well as in the uncovered eye. The new shield presents a better appearance than the complete-occlusion type. In the unusual case of the patient with loss of vision in one eye it allows the wearing of a shield over the good eye.

Advantages in therapy are anticipated. Any final determination, however, that it

shortens the time of eye inflammation or lessens complications or sequelae must await a longer period of study and more accurate data. So far the new shield has not been used in the usual postoperative case. Its efficiency in certain stages of postoperative care seems plausible. When protection from light is not needed the use of the clear shield more nearly allows normal binocular vision than that allowed by the tinted type. However the usual requirements are for light protection. Occlusion of one eye in the treatment of amblyopia, in the temporary treatment of diplopia, and in taking fields obviously requires complete occlusion.

CASE REPORT (GROUP 1)

Mr. J. M., aged 55 years, on August 12, 1937, while employed as a millwright in a grain elevator, was struck in the right eye by a small iron bar. At the time he was not wearing glasses. His distance vision had always been good. In late years with reading glasses his near vision had been satisfactory. Other history was of no importance.

Examination (one hour after accident): R.V. 1. -3, L.V. 1. -4; with +2.00 D. add., each eye—J.1 at 14". There was a one-half inch vertical laceration of the right bulbar conjunctiva, 7 mm. medially from the corneoscleral junction. The adjacent conjunctiva was hyperemic. Except for a moderate retinal arteriosclerosis, the findings were otherwise negative. After the wound healed, the patient did not return for retinoscopy and phoria tests.

Treatment and progress: Under asepsis the conjunctiva was sutured with black silk. One drop of 1-percent atropine was instilled on the first day only. For three days 1-percent yellow oxide of mercury ointment was used, and the eye was bandaged. During this time there was the usual traumatic reaction; that is, the conjunctiva was injected and swollen. On the

fourth day, the patient returned to work wearing the complete-occlusion type of shield. Oxycyanide of mercury 1:5000 was given for home use. The condition improved steadily. On the seventh day, the sutures were removed and the following day a transparent shield replaced the old shield. This was worn continuously for three days and because of the presence of grain dust in his place of employment it was worn at irregular intervals for another week. After wearing this shield for 24 hours he stated that his eyes felt a great deal more relaxed. The relative objective findings on this day were not definite but the eyelids appeared more relaxed and the tissues less congested. The patient later stated that the shield was moderately comfortable and only caused a slight interference with his work.

Results: The wound healed without any complications. A thin scar remains and the vision was unchanged.

SPECIAL PROBLEM OF GROUP 2

In the presence of free lacrimation (from whatever cause) or excessive perspiration, with the additional factors of humidity and atmospheric-temperature variations, the inner front piece of the shield becomes clouded with fine or coarse moisture. This disturbs proper vision and one may be forced to pad the shield with cotton.

By making a few openings in the shield, allowing ventilation, this difficulty was overcome so that the shield was worn with comfort. In these cases a circular aperture 6 mm. in diameter was made with an inexpensive hand punch in mid line about one-half inch from the lower edge of the shield. One was made over the region of the inner canthus, and the last over the external canthus. The part of the shield selected for each aperture must be elevated from the skin.

The possible danger of secondary infection in using the ventilating shield must be considered, consequently discretion is necessary in the choice of eye cases and the environment in which its use is allowed. However, in a reasonably clean atmosphere this danger appears to be reduced rather than increased. The small number of cases in which ventilation has been used seem to have responded more favorably to treatment than usual.

This was particularly noticeable in the case of ocular burn mentioned, in which the healing time seemed considerably shortened and the succulent edematous appearance of the tissues disappeared on the first day that the new treatment was instituted (third day after the burn).

In considering this principle of treatment one may reason that the real source of danger is the stagnant pool of secretion, while free lacrimation and later relative dryness both discourage bacterial invasion.

When purulent secretion is present a cotton pad should be used, likewise in those cases in which there is visual obstruction from moisture and an unfavorable environment the use of the ventilating shield is inadvisable. Both of these conditions frequently exist for only a part of the time while the patient is under care.

A loose pledget of cotton or a piece of gauze over the lower opening of the shield may be used as an air filter in some cases.

PHYSIOLOGY

The primary objective of the lid muscles is for preservation of the eyeball. Opening the lids to allow vision should be considered secondary. This protective action is two-fold in purpose. It closes the lids, forming a shield, and it distributes the lacrimal secretion over the delicate anterior tissues of the eyeball.

Bell³ in his classical essay of 1823, showed that this protective mechanism of

lid closure is supported by a special action of certain ocular muscles: briefly, in sleep and certain other occasions the lids are incompletely closed, the eyeball is rolled upward and outward, thereby improving the position for the two-fold protective action. The lid closure is brought about by the palpebral portion of the orbicularis oculi muscle. This muscle is highly sensitive and has a low chronaxie of 0.20 to 0.36 sigma (Bourguignon⁴). The second part of this phenomenon is due to the action of the superior rectus muscle. The sensitiveness of this composite action has been described by Miles,⁵ who in his experimental work has demonstrated the efficient manner in which the eyeballs turn upward regularly even in winking. He states that the results were practically the same for binocular or monocular closure. An important consideration is that while these two actions are associative the turning of the eyeball depends upon the primary action of lid closure.

In the establishment of the artificial condition of monocular occlusion there is an immediate variable loss of vision. The amount of this depends upon the percentage of vision in each eye, and also upon which eye is covered. Most patients find some difficulty in monocular vision, and the decrease in sharpness of vision discourages any prolonged attempt at close work, especially reading. Where vision is forced in this condition it is logical that the ciliary muscle undergoes a strain. The change from the binocular field to that of the monocular type is not an important factor in causing muscle strain.

With monocular occlusion, the heterophoric eye will not react in the same way as does the orthophoric eye. The manner and degree of this difference will depend upon the amount of heterophoria and upon which type of phoria is present; that is, esophoria, exophoria, or hyperphoria. Bielschowsky⁶ states that orthophoria is

the exception, that at least 80 percent of eyes are heterophoric. Marlow⁷ reports an even greater figure.

With monocular occlusion in heterophoria certain changes in the position of the eyeball and extraocular muscles take place immediately. Marlow⁸ has shown that the relaxation of heterophoric muscles under monocular occlusion at first is incomplete. Effort towards convergence in this early stage must throw an added burden on the individual heterophoric muscle. Increased muscle action occurs in a mild degree also in the remaining extraocular muscles because of the necessary readjustment. It is only when the stage of decompensation is reached that these conditions practically no longer exist. This is the time when the fusion tendency reaches its lowest limits.

A different phase of this problem relates to the lid muscles working in association with the vertical muscles of the eyeball. Certain innervational influences are present in the eye that is actively fixating. The action of the levator palpebrae superioris elevates the eyelid. Besides convergence and accommodation the entire musculature is in tone, and the eye is in constant albeit imperceptible motion. Adler and Fliegelman⁹ have shown that in fixation there is continual motion and that fatigue and lag of attention cause an increase in the rapid shifts. We may presume that this latter stage is frequently the transitional period before physiologic rest.

In the inattentive eye the absence of fixation relaxes the muscles of accommodation and convergence and the eyeball has a tendency further to relax to the position of rest. Adler,¹⁰ states that when a person is fatigued the tone of the lid muscle innervated by the sympathetic system is depressed and the palpebral fissure becomes narrower. That a similar condition due to monocular occlusion is experi-

enced when local fatigue sets in it is reasonable to assume. It is then that the lids frequently blink and that innervation for lid closure increases. Associated with this is the innervation effecting the upward turning of the eye at each incomplete closure.

With monocular occlusion a conflict between these two innervational forces frequently exists. The extent to which this influence is felt must depend upon the relative amount of these special innervations to either eye. It is probably greatest when that stage is reached in which the two separate innervations are comparatively equal.

It is this conflict that creates a muscular imbalance and brings about excessive innervation to the lids, resulting in tremor and later blepharospasm.

In my opinion this tremor and blepharospasm acting through Bell's phenomenon are frequently productive of so-called functional hyperphoria, in which cases it may be associated with true latent hyperphoria.

An understanding of this muscular tremor may be had by establishing a vertical diplopia with prisms. This is done by increasing the strength of the prisms just beyond the point of duction; then, with a partial contraction of the lids of one eye, the light will be seen to waver. A coarse fluctuation will first be noted by the eye with the partially closed lids. In a short time a fine fluctuation is frequently noted in the other eye.

Of additional interest is the anatomic relationship.¹¹ The levator palpebrae superioris inserts its stronger posterior lamella into the upper margin of the superior tarsus and attaches itself to the conjunctiva.

With this fact in mind we may reason that the presence of blepharospasm in an injured or diseased eye will cause increased conjunctival congestion.

Certain branches of the ophthalmic artery supply the extraocular muscles. These end as anterior ciliary arteries. The corresponding veins empty into the veins of the extraocular muscles. Again, in the pathological eye an increased innervation of any of these muscles might be presumed to aggravate the congestion already present.

SUMMARY

The conclusion drawn from a rather brief empiric study favors the use of the properly made transparent shield over the type of shield that produces complete monocular occlusion. This conclusion is apparently supported by certain physiological findings.

The new shield is used unchanged, provided with ventilation and with cotton padding. The ventilating shield should be used only in a favorable environment and for the suitable type of case. Otherwise, the amount and character of secretion determine the choice.

When properly used certain advantages

are noted in the new type of eye shield. The wearer will have vision in both eyes, thereby allowing a reduction of incapacity in occupational activity and in recreation. It reduces both local and general nervous tension. A better appearance is noted.

In the hyperemic eye, a certain amount of nervous and muscular irritation already exists. Anything which induces nervous tension in the inflamed eye would increase the engorgement in the conjunctival and adjacent tissues.

One of the fundamental therapeutic principles is that rest is necessary to promote the healing of diseased or injured tissues. While complete rest is not always possible, in those cases where only an eye shield is indicated, a greater degree of relaxation is obtained by allowing vision. By properly using a transparent eye shield, one accomplishes this and still gives the necessary protection to the eye.

The effects of monocular occlusion are presented.

SUPERFICIAL MARGINAL KERATITIS

CLINICAL AND ANATOMIC FINDINGS IN FELLOW EYES*

O. H. ELLIS, M.D.

Saint Louis

Superficial marginal keratitis, according to Isakowitz,¹ was first described in 1881 by Arlt. In his "Textbook of ophthalmology," E. Fuchs,² in 1895, gave a full discussion of the signs and symptoms of this condition, which were also included in the later editions of his excellent work.

F. Schieck³ presented, in 1931, a summary of the types of marginal ulcerations of the cornea. He divided marginal ulcers into six groups: (1) Catarrhal marginal ulcer. (2) Infectious marginal ulcer. (3) Traumatic marginal ulcer from infarcts of the meibomian glands. (4) Marginal ulcer over an arcus senilis as a trophic disturbance. (5) Marginal ulcer in keratitis from rosacea. (6) Marginal ulcer of metastatic origin. The cases presented below fall into the fourth group and following Fuchs's terminology may be classified as superficial marginal keratitis.

Gilchrist⁴ described a case quite similar to those here described. Her patient presented bilateral extensive superficial marginal ulcerations which progressed in spite of all treatment. The article was entitled ". . . keratitis marginalis profunda . . .," but the final paragraph stated that the case had progressed as described by E. Fuchs under the heading of superficial marginal keratitis.

W. A. Martin⁵ in 1899 and 1900⁶ presented four cases of this classification in which he carefully described the symptoms and gave photophobia as the most distressing subjective complaint. This author thought the condition was a pri-

mary involvement of the cornea and not superficial marginal keratitis as described by E. Fuchs.

In the Chinese literature, Soudakoff⁷ reported five cases in patients who also had trachoma. In addition he included an incomplete discussion of four more patients. From the descriptions, the cases markedly resembled superficial marginal keratitis. Nevertheless, one hesitates to include these cases, since all the patients exhibited a trachomatous state.

In an article, entitled "The changes of old age in the human eye," G. Attias⁸ accurately wrote concerning this condition. Microphotographs were included which clearly showed the changes characteristic of superficial marginal keratitis, although the author failed to point out or describe the histologic changes.

The first patient of the present report had superficial marginal keratitis in both eyes with unusually severe subjective and objective symptoms, necessitating bilateral enucleation. The second patient also had this disease in both eyes. In the second case, only the clinical changes can be described.

REPORT OF CASES

Case 1. The patient, a 65-year-old white male, married, was first seen in the eye clinic at Washington University, on June 26, 1930. The chief complaint was an inflamed left eye with intermittent pain for preceding two months.

While at work two months before, lime and sand had blown into the left eye. The patient went to a general physician who treated him for about two to three weeks. After this, the eye was improved

* From the Department of Ophthalmology and The Oscar Johnson Institute, Washington University Medical School.

and the patient returned to work. About three weeks later (six weeks following the injury), the left eye again became sore and he returned to his physician. This recurrence of the inflammation persisted and became worse in spite of all treatment. The latter had been continuous until one week previous to his visit at the clinic. The vision had become markedly impaired and the eye remained extremely painful. The patient had had complete dental extractions since the onset of the present illness, but this had no effect in altering the course of the condition. There had been no constitutional symptoms. In the history, the patient stated that he had always had frequent headaches. The appetite had become unusually poor, but without any nausea or vomiting. He was constipated and had a chronic cathartic habit. He had nocturia and for the preceding two to three weeks had had some pain and burning on urination, but without any hematuria.

Examination: In the right eye was a small corneal scar near the limbus at the 7-o'clock position. Vision was 6/30 without correction. The findings were otherwise negative for this eye. The vision of the left eye was the ability to detect hand movements at one meter. The bulbar conjunctiva was reddened. There was present a superficial ulceration of ring form completely surrounding the cornea. The corneal center for about 4 mm. in width was fairly clear. Numerous small blood vessels extended from all directions into the cornea. The pupil was wide and the iris indistinctly visible. The globe was very sensitive to palpation. The impression at this time was multiple marginal ulcers of the cornea. Protargol, atropine, and holocaine ointment were prescribed. The patient was seen in the clinic on the following two days, and the eye condition did not change.

On July 1, 1930, the patient was ad-

mitted to Barnes Hospital for treatment of the corneal ulcers of the left eye. The general examination was essentially negative except for a moderate degree of emphysema. The blood pressure was 164/84. The examination of the urine was negative. The patient was given infra-red therapy in addition to the local treatment prescribed in the clinic. By July 3, 1930, the ulcerations covered the cornea except for a small area over the pupillary region and the vision was reduced to light perception. The patient was suffering considerably, and, as he had not responded to treatment, enucleation was advised and carried out.

On July 21, 1930, the vision in the right eye was 6/30 and with correction of +1.50 D. sph. \approx +1.00 D. cyl. ax. 90°, the vision was improved to 6/10. The patient came into the clinic eight days later with the right eye somewhat irritated. Examination showed no ulceration or infection. A solution of zinc sulphate was prescribed for use at home. At the next visit 10 months later, May 1, 1931, the patient complained of poor vision in the right eye. He stated that he had had redness and pain in the eye for several days, two months previous to this visit. This trouble had been relieved with home remedies. Examination of the eye on May 1, 1931, showed some peripheral marginal corneal scarring, but no active lesions. Although the center of the cornea was transparent, the center of the lens showed incipient senile-cataract changes, making a clear view of the fundus impossible. The patient was seen on May 15, 1931, and the examiner was unable to improve the vision of 6/30 with any lens. The eye was comfortable at this time.

After an interval of 16 months, the patient returned to the clinic on September 29, 1932, stating that for the past seven days his right eye had been painful. Examination showed an intense circum-

corneal injection. There was observed an ulcer of the cornea involving the superior nasal marginal portion. Several marginal corneal scars were present. A red reflex from the fundus was present but no details were visible. The vision was 1/60 without correction. The patient was given local treatment with weak solutions of silver nitrate and zinc sulphate and told to use hot compresses at home. On a later visit a pseudopterygium with a small area of staining at its pupillary edge was noted. There was present at this time no active process in the cornea as indicated by the lack of pericorneal injection. On October 12, 1932, the tension of the eye was normal and there occurred no staining of the cornea with fluorescein. Examination one week later showed a small superficial vesicle on the cornea just outside the pupillary area at the 10-o'clock position. Shortly thereafter, the cornea healed, and the eye was free from injection and pain.

About 14 months later, the patient again came to the eye clinic. Because of the seriousness of the findings in his remaining eye, he was immediately admitted to the hospital. He said that the right eye, in the previous six months, had gradually become more painful. The patient had not consulted any physician. The pain had become almost unbearable and the vision had been completely lost for the past three weeks. Examination at this time showed a central loss of epithelium about 4 mm. in diameter. The remainder of the cornea was completely vascularized and covered by a pseudopterygium. The bulbar conjunctiva was injected and edematous. On account of the loss of all vision and the intense degree of pain, enucleation of the right eye was performed on January 3, 1934.

Anatomic observations in left eye. The anterior epithelium of the cornea was generally absent, probably being desquamated, as is common, at the enucleation.

In the periphery of the cornea, adjacent to the limbus on each side, there was present a ring-form ulceration. This ulceration was wider on the nasal side, where it involved about one third of the diameter of the cornea. On the temporal side, about one fourth of the corneal width was ulcerated. The depth of the ulceration was greater also on the nasal than on the temporal side, being about one fourth of the corneal thickness at the former and about one fifth at the latter site (fig. 1). The depth of the ulceration was greatest at about halfway between the corneoscleral junction and its central corneal margin. This ulceration had destroyed the superficial corneal lamellae including Bowman's membrane. Infiltration with pus cells was especially intense in the cornea below the ulcerated areas. In the uninvolved center of the cornea, pus cells occurred in moderately dense numbers between the corneal lamellae. In addition there was observed an intense, diffuse proliferation of the fixed corneal cells or corneal corpuscles. A few small blood vessels were observed in the ulcerated peripheral portion of the cornea, both superficially and lying deeply between the lamellae of the cornea. An intensely infiltrated and highly vascularized bulbar conjunctiva was seen everywhere overlapping the corneal limbus and producing a pseudopterygium, thus forming in most places a reduplication of the stratified squamous-cell epithelium (fig. 2). This pseudopterygium was present in the entire corneal circumference, extending nasally over the entire width, temporally only a part of the width of the ulcerated area. From this pseudopterygium, the squamous-cell epithelium was solely derived. The epithelium covering the middle portion of the corneal ulceration had proliferated inwards from the apex of the pseudopterygial fold. This epithelium varied greatly in thickness from several flattened layers up to that of

an epidermal covering. In some places, there were present areas of considerable extent possessing keratinized or horny outer layers.

The uveal tract was generally atrophic,

of secondary degeneration as was manifested by small, clear, cystic spaces in the ganglion-cell layer. The optic papilla contained, nasally, many small and large, irregularly formed masses of amylaceous

Fig. 1 (Ellis). Left eye. Section through cornea with superficial marginal keratitis showing to the right a deep loss of substance from ulceration covered by stratified epithelium and to the left only a superficial loss of substance uncovered by epithelium; under the latter area, the cornea propria presents much proliferation of the corneal corpuscles and considerable infiltration with pus cells. ($\times 90$)

Fig. 2 (Ellis). Left eye. Section through cornea with superficial marginal keratitis at apex of pseudopterygium showing to the left a covering stratified epithelium together with a deeply lying stratified epithelium. In the subjacent cornea propria, numerous pus cells are infiltrating between the constituent lamellae, and an intensive degree of proliferation of the corneal corpuscles occurs. ($\times 130$)

and melanin could be observed wandering out of the dilator pupillae muscle and from the pigmented epithelium of the iris, ciliary body, and retina. Pigment from these sources lay in the iris-angle and on the filtration trabeculae. The uveal tract showed practically no cellular infiltration. There was present a broad posterior adhesion of the pigment epithelium to the anterior surface of the lens. The lens showed an incipient senile cortical cataract. The retina presented a small degree

bodies. The optic nerve was moderately atrophic.

Summary: Superficial marginal ulceration with overgrowth of a pseudopterygium was observed. The pseudopterygium here, unlike a true pterygium, was everywhere closely adherent to the underlying structures. The internal epithelium, lying just superficial to the corneal ulceration and due to the overgrowth of the conjunctival fold, had disappeared in some places.

Anatomic observation in right eye.

The anterior epithelium was present over the entire cornea. Its thickness varied from two to three layers of flattened cells up to a very thick stratified squamous-cell epithelium. As in the fellow eye, a ring-shaped ulcerative process of the corneal margin was present (fig. 3). The latter was more extensive nasally, extending over the entire nasal half of the cornea. Temporally the ulceration involved but little more than one fourth of the width of the cornea. Hence an area of

cells occurred in many places in the floor of the ulcer. At one place, on the nasal side in the floor of the ulcer, there were observed numerous epithelioid cells and a few foreign-body giant cells (fig. 4). The latter were undoubtedly produced by a reaction to some chemical substance. Also unlike the fellow eye, there was present in places, new-formed connective tissue or cicatrization, indicating an attempt to heal the ulcer. In the middle of the cornea, there occurred very few pus cells between

Fig. 3 (Ellis). Right eye. Section through the entire width of the cornea with superficial marginal keratitis showing peripheral loss of substance and accompanying cellular infiltration. ($\times 9$)

less than one fourth the corneal diameter remained unaffected. This paracentral portion was covered with an extremely thin epithelium consisting of three to five layers of flattened cells. Only in this part of the cornea was Bowman's membrane present. The depth of the ulceration extended to about one fourth the corneal thickness at its deepest place, both nasally and temporally. The loss of substance from the ulceration involved to a greater degree the medial two thirds of the nasal portion and the central part of the temporal portion of the cornea. The ulceration had generally destroyed Bowman's membrane and the superficial lamellae of the cornea propria. In this eye the infiltration with pus cells at the site of the ulcer was not so intense as in the left eye. On the other hand, on account of the length of time the inflammation had continued in this eye (four years), small round

the corneal lamellae. The proliferation of the fixed corneal cells was slight except adjacent to the ulceration. Blood vessels were noted just beneath the epithelium in the ulcerated areas.

The bulbar conjunctiva of this eye adjoining the cornea was swollen in varying degrees from dense infiltration with small round cells, congested blood vessels, and edematous fluid. It had overlapped the corneal margin in its entire circumference to form a pseudopterygium (fig. 5). The reduplication of the epithelium from the latter extended inwards nasally for about one half the width of the ulceration. Temporally, no second underlying epithelial layer was present. It is possible that a pseudopterygial fold occurred, and that in time the deeply lying epithelium disappeared. Only very slight keratinization was noted covering the surface epithelium on the nasal side.

The uveal tract was atrophic and there was observed the wandering-out of melanin from the pigmented epithelium of the iris, ciliary body, and retina; however, these changes were not so extensive as in the left eye. There was little pigment on the filtration trabeculae. The uveal tract

and had almost entirely disappeared from the remainder of the retina. The optic papilla was a little swollen and the retina was pushed away from the optic nerve, particularly on the nasal side. On the latter side the optic papilla contained many large and a few small, irregularly formed

Fig. 4 (Ellis). Right eye. Section through cornea with superficial marginal keratitis showing epithelioid and giant cells to the right in the floor of the ulcer. In the subjacent cornea propria, a moderate degree of infiltration with pus cells and proliferation of the corneal corpuscles are present. ($\times 160$)

Fig. 5 (Ellis). Right eye. Section through cornea with superficial marginal keratitis showing apex of pseudopterygium and two layers of stratified epithelium to the right. Numerous small round cells are present in the floor of the ulcer to the left and in the subepithelial connective tissue of the conjunctival fold to the right. ($\times 140$)

showed almost no cellular infiltration. In the lens was seen minute evidence of an incipient senile cortical cataract. The retina presented a secondary diffuse cystic degeneration particularly in the rod-cone and ganglion-cell layers. The fovea centralis also showed an intensive secondary degeneration and replacement of its constituents with edematous fluid. The ganglion cells were present in normal numbers only around the fovea centralis

masses of amylaceous bodies. The optic nerve was moderately atrophic.

Summary: An extensive superficial marginal ulceration of long standing was present. A pseudopterygium here also partly covered the ulcerated area. The layer of epithelium lying deeply over the ulcer, and due to the pseudopterygium, had largely disappeared. It was interesting to note in the optic papillae of both eyes amylaceous bodies accompanying

the degeneration of the retina.

Case 2. The second case concerned a 70-year-old white female who entered the Washington University Out-Patient Department in April, 1938, complaining of burning and watering of the eyes for the past two years. Examination of the eyes showed a moderate congestion of the conjunctival blood vessels of the eyelids of both eyes. The corneae of both eyes exhibited an annular, bluish-gray, marginal zone extending from near the limbus inwards about 3 mm., and superiorly for at least $3\frac{1}{2}$ mm. The central margin was indistinctly demarcated from the normal cornea. A uniformly narrow, clear, circular interspace was noted peripherally to this bluish-gray zone. No arcus senilis was present; however, this bluish-gray zone was in the usual position of the arcus senilis. In the left eye there were observed two whitish superficial linear opacities, about 2 mm. long, lying within the bluish-gray marginal zone nasally and inferiorly. Under examination with the slitlamp and corneal microscope, the bluish-gray peripheral zone in each eye appeared to be inflammatory infiltration of the superficial corneal lamellae, and the whitish linear opacities were shallow depressions with very small, superficial blood vessels extending to them from the nearest part of the corneal limbus. These linear opacities were undoubtedly superficial scars probably resulting from an ulceration. When the patient was last seen there existed a faint yellowish opacity extending centrally, within the bluish-gray marginal zone, from each of these linear scars. This apparently indicated some activity. There was never present any staining of the cornea with fluorescein while the patient was under observation. The right eye examined with slitlamp and corneal microscope showed a small, superficial, whitish circular area about 1 mm. in diameter at the 5-o'clock position. This was also

vascularized, and likewise lay entirely within the bluish-gray marginal zone. The remainder of the ocular examination was entirely negative except for very early cortical lens opacities of both eyes, and a minimal degree of arteriolar sclerosis of the retinal blood vessels. The two latter changes were entirely in keeping with the patient's age. The vision, taken with the Snellen test chart, was 6/10 for each eye and with the correction of +1.50 D. sph. \ominus +.25 D. cyl. ax. 90° for each eye, the vision was improved to 6/7.5. With an addition of +2.50 D. sph. the patient read Jaeger 2 at 33 centimeters.

The patient also gave a history of morning cough with expectoration of one-quarter to one-half cup of sputum, which, however, was never streaked with blood. The patient's husband, one brother, and two sisters had all died of pulmonary tuberculosis. Examination in the medical clinic revealed râles in the apex and base of the right lung. The blood-pressure was 160/65 mm. of mercury. Bronchiectasis was diagnosed and the patient put under appropriate treatment.

DISCUSSION

Fuchs² describes superficial marginal keratitis as a rare disease occurring in persons of middle and more advanced age. A superficial ulceration spreads irregularly over the cornea, starting from the periphery. The ulcerated margin is indistinctly demarcated from the transparent central portion by a fine gray line. This ulcer is extremely shallow, and its edge is not undermined. Superficial marginal keratitis is characterized by numerous remissions and recurrences over a period of years. Pseudopterygium commonly accompanies it. The patient usually complains of a mild discomfort of the eyes, although in our first case and in that presented by Gilchrist,⁴ the symptoms were those of extreme pain. There

is present at first a grayish, peripheral infiltration of the cornea which becomes yellowish with the ulceration. Schieck³ is of the opinion that these ulcers develop in the corneal periphery as a simple loss of substance due to a deficient nutrition, the latter being indicated by the fatty infiltration of this region. He therefore, considers the process to be of endogenous etiology. Schieck notes that there is usually seen the interval of clear cornea (about 1 mm. wide) adjacent to the limbus, and that these ulcers lie entirely within the zone of the arcus senilis.

It must be kept in mind that these cases are not those of marginal dystrophy or furrow keratitis. Gifford⁹ does not believe that marginal dystrophy occurs on the basis of an arcus senilis. The two conditions (superficial marginal keratitis and marginal dystrophy) are quite distinct according to Doggart.¹⁰ The latter states that approximately one third of some 80 patients with marginal dystrophy described in the literature were under 40 years of age and in a few instances under 20 years. In several instances, the absence of arcus senilis in furrow keratitis in

elderly individuals has been specifically mentioned. Furrows have also been observed as separate from and bearing a peripheral relation to an arcus senilis.

Up to the present time there have been presented in the literature 5 cases of superficial marginal keratitis, not including the two described here. Much of the contributions on marginal keratitis to be found in the literature concerns marginal dystrophy, and also hereditary corneal conditions occurring in children.

CONCLUSIONS

The first case of superficial marginal keratitis herein described presented severe bilateral involvement, which greatly interfered with vision and caused intense pain, necessitating the enucleation of both eyes. Opportunity was thus offered for describing the anatomical findings in this condition. This is the first time that the anatomical findings of superficial marginal keratitis have been published. A second case with the clinical findings of superficial marginal keratitis is reported.

CONGENITAL ABDUCENS PARALYSIS

CARL APPLE, M.D.
Chicago

The reason for reintroducing the subject of congenital abducens paralysis is two-fold: (1) To bring this subject to the fore again and review some of the work of Alexander Duane,¹ Julius Wolff,² Harold Gifford,³ and Robert Salus,⁴ who devoted much of their time to the study and description of this condition. (2) To report 15 cases that were seen at the University of Illinois Eye Clinic during the past 10 years. Three patients in this group came under my own personal observation and were operated upon to determine the anatomic condition of the internal and external recti muscles, and to correct the associated strabismus.

In this paper I shall refer to the condition, as did Dr. Harold Gifford in 1926, as congenital abducens deficiency. It is not a common condition. In 1905, Alexander Duane reported 54 cases, six of which were his own. Julius Wolff wrote that a certain feature of this condition, namely retraction, was first brought to his attention in 1899 by Türk, and that only seven cases were reported up to 1900. Dr. Harold Gifford saw his first case in the early '90's; by 1926 he could bring the total number of reported cases to 105 monolateral and 34 bilateral; he added to these 30 monolateral and 9 bilateral cases from his own practice.

As is well known, congenital abducens deficiency occurs most frequently in females and involves the left eye more often than the right. In our series of 15 cases there were 9 females and 6 males, or 60 percent females, which compares with Dr. Gifford's 60 percent and Dr. Duane's 70 percent. Four of the 15 were bilateral, 11 monolateral; of the latter, 9 had the left eye involved. This also is in

agreement with the statistics of other writers.

Seven of our group were hyperopic with moderate astigmatism, one myopic, and another had an astigmatism of three diopters. Of the 11 monolateral cases, 6 patients had orthophoria, 4 convergence, and 1 had a divergence. Of the bilateral cases, 2 patients had orthophoria and 2 convergence. These findings are consistent with those of other investigators.

The cause of left-eye preponderance is still unknown. In 1926 Dr. Gifford discussed this from a birth-injury standpoint. He cited Hoefnagel, who called attention to the fact that left occiput anterior presentations occur in 70 percent of normal births. In this position, during the rotation of the skull, the left temple would be forced against the promontory and the pressure might cause an anemia which, if long continued, could induce the degeneration of the externus muscle into a fibrous band. He also called attention to Leser's experiments which showed that a pressure anemia of two to three hours produces a myositis followed by nearly complete regeneration of the muscle, but if the pressure continued for five to six hours, the greater part of the muscle underwent fibrous degeneration. He concluded, however, that birth injury has not been found the cause of congenital abducens deficiency in any case. The excess of left-eye involvement is considerably greater than is the left occiput anterior position over the other presentations. He also cited a typical congenital abducens deficiency case in which delivery was by Caesarian section.

Congenital abducens deficiency is manifested by a group of objective findings.

Some of these are present in all cases to a greater or less degree, and others may or may not be present in some. Among the important objective findings are: (1) restriction of abduction; (2) restriction of adduction; (3) retraction; (4) oblique upward and downward movements; (5) protraction; (6) insufficiency in convergence; (7) torsion movements. This group of symptoms constitutes Duane's syndrome.

Restriction in abduction may range from slight deficiency to that of complete absence. In those who possess some abduction power, this becomes more marked on looking up and out or down and out. An outstanding feature is the absence of contracture of the internus in spite of the completeness of the apparent paralysis of the externus.

The retraction phenomenon has been the subject of greatest controversy. It may be absent in a small percentage of cases or it may range from 1 to 10 millimeters. In 1900 Julius Wolff devoted a great deal of space to theorizing on this particular point. He described retraction as "that condition when by the contraction of one or more of the external ocular muscles, the eyeball is drawn back into the orbit, and returns to its former position when the contraction ceases." He quoted Tuerk, who in 1896 suggested two possible theories: (1) the faulty-insertion theory, and (2) the fixation theory.

According to the *faulty-insertion theory* the retracting muscle, which is the internal rectus, is attached to the eyeball farther back than the normal attachment; consequently, the portion of the muscle capable of unwinding itself from the globe is diminished and inward rotation is correspondingly replaced by a backward pull on the globe when the internal rectus contracts.

In advancing the *fixation theory*, Tuerk assumed that the paralyzed external rec-

tus consists of an unyielding connective-tissue band in place of the elastic fibers. It therefore fixes the eyeball on the outer side and offers an obstacle to adduction, so that the eye can yield to the traction of the internal rectus only by moving back into the orbit at the same time that it turns inward. This theory, however, does not explain the occurrence of retraction when there is no power of adduction. Some writers, as Parker,⁵ Peschel,⁶ and Schapring,⁷ were of the opinion that the retraction is caused by the superior and inferior recti. They supposed that in those cases where the action of the internus was ineffective, the superior and inferior recti, by contracting very strongly and by acting vicariously as adductors, would pull the eye back into the orbit.

Wolff proved the inelasticity of the paralyzed external rectus muscle in several cases by the fact that even strong traction with the forceps could not produce pure adduction.

Stilling⁸ operated upon his patient in order to cure the divergent strabismus. He advanced the internal rectus, which was found to have a normal insertion. The result was that the retraction became even more pronounced than before.

Wolff also operated on one of his patients in order, if possible, to cure the retraction. He found both the external and internal recti normally inserted and divided the external in the hope that it would reattach itself farther back. The immediate result of the operation was that the slight abduction originally present was lost, adduction increased and the retraction was no longer to be seen. After the muscle had reattached itself, however, the condition was just as it had been before. He concluded that since a normally inserted internal rectus caused retraction of the globe, there must have been some fixation on the outer side

by the external rectus short muscle.

Thirty-four years later, in 1934, Professor Salus came forward with additional findings that help to disprove Hueck's fixation theory, which Wolff had accepted as the most plausible. Salus started with the supposition that if the external rectus is the cause for the retraction, then the retraction should disappear when the muscle is severed from the sclera at its insertion. He cited three cases of typical congenital abducens deficiency with retraction in which he operated. In all these cases, neither the retraction nor the associated squint showed any changes when the externus had been severed. After resuturing this muscle and then tenotomizing the internus, he still found no change in either the retraction or squint. But in two of the three cases he found, as others have found, a muscle band underneath the internus which was attached to the sclera closer to the equator. When this was severed both the retraction and strabismus disappeared, and a certain amount of abduction became possible.

He is of the opinion that in many cases these medial bands are responsible for the lack of abduction and the retraction. Further, since these bands have existed since birth, not permitting any function of the externus, he believes that changes of the externus, such as the disappearance of muscle fibers, connective tissue, and fatty degeneration, are secondary.

Working along the line of thought of Professor Salus, I also attempted to look for pathology in the region of the internal rectus. In two of my cases I was able to demonstrate muscular bands underneath the internus and in the third there was a fan-shaped addition to the internus proper.

Case 1. L. N., a girl, 11 years of age, had typical evidences of left congenital abducens deficiency. Here I found a 4-mm. wide muscular band running under-

neath the internal rectus muscle. It was inserted obliquely and somewhat posteriorly to the original insertion and extended for about $1\frac{1}{2}$ cm., then joined the inner aspect of the internus. *Passive abduction* after tenotomy of the internus still met with resistance, but, after severing this band, the eyeball became freely movable in all directions. The externus, on the other hand, appeared like a grayish connective-tissue cord; no distinct muscle fibers were noted. Later the palpebral fissure appeared somewhat wider, the retraction seemed less, and a slight amount of abduction became possible. I failed to excise this muscle band. When last seen on April 13, 1938, there still was present 10 degrees of abduction; adduction was not improved, and the palpebral fissure was slightly wider than it had been prior to the operation.

Case 2. M. K., a girl, 3 years of age, had a right congenital abducens deficiency and an associated 20-degree convergence. Here, also, I found a muscle band stretching from below the internus to the bulbus, attaching itself a little posterior to the normal attachment. As in case 1, passive abduction met with resistance after tenotomy of the internus, and the convergence was unaltered; but when the band from the scleral attachment was severed, the eyeball became freely movable. I did not investigate the externus in this case. The internus was receded 3 mm. Twelve days after the operation, the eyes were parallel and abduction was markedly improved; the palpebral fissures were of equal size. The child was moved to Montana but the parents coöperated and sent me the pictures and information I requested. It seems that abduction is present and convergence has been corrected. The mother writes that the child's eyes are in good position and the palpebral fissures are of equal size.

Case 3. B. B., a girl, $6\frac{1}{2}$ years of age,

had a typical left congenital abducens deficiency and an associated convergence of 10 degrees. Here, no muscle band was found, but the internus appeared thicker than normal and there was a fan-shaped addition at its insertion. The externus did not appear completely fibrous; definite muscle tissue could be discerned. A mild recession of the internus was performed. When last seen on April 13, 1938, the eyes were in parallel position, about 12 degrees of abduction was present, and the retraction which formerly was about 3 mm., was now questionable; the palpebral fissure was a little wider in the primary position than it was prior to the operation.

Of the other lesser discussed signs:

Adduction deficiency is most frequently encountered. It may be normal but generally it is either slightly or considerably diminished. In his series, Duane found eight cases with complete absence of adduction. In our series we found insufficiency but none with complete absence. Fixation for long in an adducted position is difficult to maintain. This finding can also be explained by the anatomic condition of the external and internal recti muscles.

The constant enophthalmos in the primary position which is observed in many cases is also readily explained by the same mechanism if we bear in mind that normally, in the primary position of the eyes, all the extrinsic muscles are in a state of slight contraction and are relaxed completely only when the antagonists contract. The *propulsion* of the globe during attempted abduction is thus thought to be due to the complete relaxation of the internal rectus.

The *oblique upward and downward movements* remain under controversy. Wolff thought them due to the resistance the optic nerve offers to the recession of the eyeball during adduction. Since the

optic nerve has a firm consistency, it offers a certain amount of resistance to the backward movement of the eyeball at its point of attachment. Unless the resistance is directly in the plane of the retraction, the effect must be to rotate the cornea upward or downward, depending on the anatomical peculiarity. Duane thought them to be due to an anomalous insertion of the internus, causing it to act partly as an elevator.

The *narrowing of the palpebral fissure* on adduction is apparently due to the natural position of the lids in their relation to the position of the eyeball, although some writers are of the opinion that the contraction of the orbicularis is partly responsible for this.

As to the *treatment* of congenital abducens deficiency, some investigators advise no operative interference, whereas others see no objection to this when the deformity is marked. Professor Salus, on the other hand, is of the opinion that bands, such as he has found in the region of the internus, can be expected in many of these cases; they should be investigated and excised. In one of my cases I found a definite improvement in abduction as well as in the squint; in another the squint was corrected; in two, a slight amount of abduction remained possible and the retraction lessened. I see no objection to investigating the status of the internal rectus muscle, especially in those cases in which there is associated strabismus. If, as Professor Salus thinks, the changes in the external rectus are due to its inactivity, caused primarily by bands of the internal rectus, would it not seem reasonable to investigate these cases as early as possible, to release these bands? The external rectus would thus be given the opportunity to develop.

Little can be done to improve abduction in those cases in which the external rectus has undergone complete degenera-

tion; however, some improvement in the retraction can be expected when muscle bands are found and resected.

In the hope that not all the muscle fibers have undergone degenerative changes, I requested two of my patients to go through systematic ocular exercises, after the operation, to improve abduction. So far there is only slight improvement following the operation, 10 degrees in one case and about 12 degrees

in the other. I do not know whether any greater improvement will be obtained; nevertheless, it is worth trying.

In conclusion, I wish to say that the last word pertaining to congenital abducens deficiency and its various phenomena has not yet been said. Further investigation is necessary to advance our knowledge of this condition.

NOTES, CASES, INSTRUMENTS

A CORNEOSCLERAL UNION FOR CATARACT OPERATIONS

PHILIP M. CORBOY, M.D.
Valparaiso, Indiana

Probably the chief reason why so many operators fail to use corneal sutures is because they do not realize what amount of handling the cornea will stand.

Fig. 1 (Corboy). Corneoscleral suture for cataract operations.

In reality, the average healthy cornea will tolerate numerous sutures for long periods and at the same time allow healing processes to take place. The healthy cornea does not become opaque from clean operative procedures, but only when pathological processes set in. The extensive trephining and suturing in corneal transplants as done by Tudor Thomas of London and by Castroviejo of New York substantiate this.

The thickness of the adult cornea will vary from 0.75 mm. to 1.2 mm., the peripheral part being the thickest. The

portion external to Descemet's membrane constitutes 95 percent of this, or from 0.6 mm. to 0.9 mm. It is through the upper layers of the cornea that sutures should be placed.

In the past there have been many objections to corneal sutures; namely, (1) The attempt to get apposition of the wound between the cornea and the sclera is dangerous because of the possibility of injuring the ciliary body, or causing undue tension and sustaining a prolapse. (2) The mattress or double-armed suture so often acts like a knife and cuts its way out. (3) The length of time necessary for inserting corneal sutures especially in the more complicated methods is too great. The objection to conjunctival sutures lies in the fact that they depend for support upon the bulbar attachment of the conjunctiva. A severe hemorrhage or prolapse under the flap can dissect up a large amount of conjunctiva.

The sutures in this new method are placed approximately at the 10- and 2-o'clock position, about 2 mm. from the limbus. The needle enters the cornea tangentially to the corneal radius and emerges 1 to 2 mm. upward. The distal end of the suture is provided with a knot at least 1 mm. in size to prevent the suture from pulling through the needle tunnel. The needle is then introduced into the episcleral tissue 5 or 6 mm. above the limbus, approximately 3 mm. laterally to the vertical line bisecting the cornea, and is directed nasalward. The second suture is then placed and the two ends are tied in a loose knot in the midline. The loops are laid to one side to permit the Graefe incision. The customary conjunctival flap is made beneath these sutures. The small

loops left available at each side can be held up by an assistant, who uses a strabismus hook for that purpose during the section and subsequent procedures. The sutures are then drawn up snugly and tied. The surgeon may perform any method of extraction he sees fit. The replacement of the iris can be accomplished after the sutures are tied. The two knots resting on the cornea are not irritating and may be left in from three to seven days, as the case may require.

The necessary equipment is: (1) corneal silk, usually .0000 or .00000 black and twisted; (2) corneal needles, either the ordinary needle of Kalt, or a smaller 10-mm. arterial needle (the important thing is not the length of the needle from tip to heel, but its thickness. A thin needle is best, necessitating a smaller knot; the only drawback of a thin needle is its fragility). (3) The needle-holder must be small and light with jaws small enough so that the needle will not roll (it must not lock, for the operator must let loose his grip on the needle instantly when necessary). (4) A fixation forceps will facilitate the placing of the sutures in the cornea, the point of fixation being usually at the opposite side of the globe.

The author has used this method of suturing during the past year with good results. At times it has been the saving grace, where nothing else would have averted disaster. In 50 cases, 3 would have failed without the suture, as vitreous prolapses were in progress. I know of no other suture that can be so effective and yet so simple. It should be emphasized that the suture must not be too tight, as there is always a little edema following the operation. The author usually removes the sutures on the fourth day, although for experimental reasons they have been left in 10 days without untoward results.

8 Monroe Street.

RETINAL DETACHMENT

REPORT OF TWO CASES WITH INTERESTING OPERATIVE RESULTS

BARNET R. SAKLER, M.D.

Cincinnati

The prognosis of spontaneous and traumatic detachment of the retina was considered hopeless until a few years ago. Gonin, in 1929, reported the results of his ignipuncture method in 81 cases of retinal detachment, and in 1932, 221 cases with 53 percent cures.¹ Since that time, his method of thermocautery has been replaced almost universally by the diathermy or electrocoagulation method. This procedure was introduced by Larson² and later modified by Weve, who changed from surface coagulation to the multiple micropuncture method. Today, the average case of so-called idiopathic spontaneous detachment of the retina can be assured of at least a 50-percent probability of reattachment and as high as 70 percent in selected cases.³ The prognosis, however, in cases of retinal detachment occurring in aphakia and in long-standing cases of traumatic origin, is still very poor. Two cases are reported in which the results obtained were thought worthy of recording.

REPORT OF CASES

*Case 1.** On July 28, 1936, M. M., a white male, aged 56 years, was admitted to the Illinois Eye and Ear Infirmary, service of Dr. Thomas D. Allen, with the complaint of failing vision in the left eye, duration of one week. No significant statements as to any probable etiological factor could be obtained. Previous ocular history was as follows: Injury to right orbit in 1924, with resultant blindness in the right eye within one year; admittance to the infirmary June 21, 1935,

* Presented before the Chicago Ophthalmological Society, October 19, 1936.

where a diagnosis of left senile mature cataract was made. An intracapsular lens extraction, using the Verhoeff technique, was performed uneventfully on the left eye by Dr. T. D. Allen. The patient was discharged July 9, 1935, wearing a correction of +10.50 D. sph. \approx + 1.25 D. cyl. ax. 180°, with vision of 20/30.

When examined this time the right eye was blind. External examination showed a very shallow anterior chamber; atrophic blue-green iris, ridged and bulging forward to touch the cornea at the lower limbus; pupil 2 mm., central, fixed; lens opaque. The fundus was not visible, the red reflex absent. Intraocular tension was 26.5 mm. Hg (Schiötz).

Vision O.S. 10/200 with no improvement on manifest refraction. External examination showed an aphakic eye with a deep anterior chamber, surgical coloboma above, iridodonesis, and no pupillary reaction to light. The pupillary area was optically empty.

Ophthalmoscopically the media were clear. The fundus presented a diffuse, fluctuating, wavy, serous retinal detachment, hanging in grayish translucent folds, uniformly elevated, 4 to 6 mm. superiorly and 1 to 2 mm. inferiorly, extending from the peripapillary area to the ora serrata, most marked from the 10- to the 1-o'clock position. No retinal tears could be found. The disc margins were well defined, the surface normal, color good, physiological excavation central, and lamina cribrosa visible. The vessels were tortuous, dark appearing, normal ratio 4:3. The macula could not be identified. Intraocular tension was 17.5 mm. Hg (Schiötz). Transillumination was negative; the red reflex was present in all quadrants. Visual field on admission was as in figure 1. A diagnosis of idiopathic serous retinal detachment was made.

The patient was kept flat on his back for two weeks with his left eye atro-

pinized. No improvement was noted. Frequent fundus examinations revealed no retinal holes. On August 14th, an operation was performed, using the technique outlined by Gradle.⁴

The postoperative course was essentially uneventful. Ophthalmoscopic examination on August 24th (10 days postoperative) showed the retina to be reattached. A linear series of black pigmented areas of chorioretinitis was noted extending anteriorly and temporally corresponding to the operative field. Confrontation method showed a definitely enlarged field. The patient remained in bed for five weeks, pinhole goggles being used after the first two weeks. The visual field was taken six weeks after the operation with results as in figure 2. Manifest refraction of +11.00 D. sph. \approx +1.25 D. cyl. ax. 90° resulted in 20/30 vision.

Examination on December 10, 1937 (16 months postoperative) showed the retina in normal position. Vision with correction was 20/20—2; visual field as in figure 3.

Case 2. On November 2, 1937, M. W., a white female, aged 12 years, was admitted to the Children's Hospital of Cincinnati for ocular study and treatment. The child complained of "blindness" in her left eye of indefinite duration. On questioning, she stated that she had been struck in the left eye and side of the head with a "kickball" about two years ago. Except for some redness and slight swelling of the eye, at that time, the incident had been forgotten. Several months previous to the present admission, the mother had noticed a drooping of the left upper lid and a tendency for the left eye to turn out.

Vision O.D. was 20/20. The external examination showed no significant findings; pupil 4.5 mm., central, reacted to light and accommodation, directly; consensual reflex to light very sluggish. The

Figs. 1 to 6 (Sakler). Visual fields in two cases of retinal detachment. Figures 1 to 3, case 1; figures 4 to 6, case 2.

intraocular tension was normal. The fundus and media were normal.

Vision O.S. was light preception and good projection in all quadrants. The external examination revealed a slight ptosis; exotropia of about 15 degrees; the pupil, 3.5 mm., reacting to light very sluggishly, irregular due to a rupture of the sphincter pupillae and posterior synchia above. Tactile tension was normal; the anterior chamber deep, optically empty.

The media were remarkably clear. The retina was completely detached, presenting a diffuse, bullous, serous detachment most marked in the upper temporal quadrant, elevated about 5 mm.; the disc was not visible, probably hidden by a fold of retina; the macula could not be identified; no retinal tears were found; no signs of retinal degeneration or inflammatory exudates were noted. Transillumination gave a red reflex in all quadrants. The visual field was as in figure 4.

General physical examination and laboratory tests such as Mantoux, Wassermann, and urinalysis, were essentially negative for any significant findings.

A diagnosis of serous retinal detachment in the left eye, traumatic in origin, was made. The question of surgery was discussed. It was felt that the prognosis was poor, inasmuch as the history indicated a time interval of about two years since the probable onset of this condition. Nevertheless Dr. Derrick Vail recommended that the patient be given the benefit of an operation.

The child was kept at absolute bed rest for two weeks, with the foot of the bed elevated. The left eye was atropinized and daily fundus examinations were made. No retinal tears were found and no improvement in the detachment was noted.

On November 20, 1937, an operation

was performed. Avertin anesthesia, supplemented with gas-oxygen, was used. The sclera, extending from the superior rectus to the inferior rectus, temporally, was exposed. A series of scleral micropunctures, by means of the Gradle needle attached to the Walker diathermy unit, was laid down and finally posterior sclerotomy with a thin Graefe knife was performed in the lower temporal quadrant. Both eyes were patched and bandaged.

The postoperative course was uneventful. The conjunctival stitch was removed on the fourth day, at which time the patient stated that she could see. One week after operation, the fundus was examined. The media were clear; there was no hemorrhage; the retina was in normal position; the optic disc, seen for the first time, was of good outline and color; the macula was not visualized; a line of discrete areas of chorioretinitis was noted, anteriorly and temporally, corresponding to the line of scleral micropunctures. Confrontation visual field was very good.

The patient was kept in bed with pin-hole goggles for three weeks. She was discharged December 24, 1937, four weeks after the operation with vision corrected as follows: O.D. + .75 D. sph. = 20/20, O.S. + 1.00 D. sph. \approx + 1.00 D. cyl. ax. 90° = 20/100 + 2. The visual field was as in figure 5.

Examination of left eye on April 29, 1938 (five months after the operation) showed the slight ptosis unimproved; the pupil, 4 mm., slightly eccentric above, reacted to light and accommodation, directly and consensually, actively; the vitreous was clear except for a few taillike floaters; the retina was in normal position; the perimacular area showed some slight pigmentary changes of chorioretinitis. Vision was 20/100 + 2 unimproved by refraction. The visual field is shown in figure 6.

CONCLUSION

1. Two cases of retinal detachment, with very poor preoperative prognosis, are reported.

2. The results obtained would seem to justify surgical intervention in almost all cases of idiopathic retinal detachment.

SULFANILAMIDE THERAPY OF INCLUSION CONJUNCTIVITIS*

REPORT OF A CASE

PHILLIPS THYGESON, M.D.

New York

Inclusion conjunctivitis appears to run a clinical course unaffected by local therapy. No one of the 9 cases in adults nor 42 cases in infants that I have been able to follow has healed in less than three months. The average time for healing has been about six months and several of the cases lasted over a year.

In a search for a therapeutic agent effective in this disease it was logical to turn to sulfanilamide, a drug which has been shown by Loe¹ and Lian² to have a powerful therapeutic effect in the related disease, trachoma. Accordingly, the drug was tested on the experimental disease in two *M. rhesus* monkeys, a daily dosage of 0.5 gr. per pound body weight resulting in complete healing of the disease in two weeks. No change in conjunctival reaction occurred in two control animals during this test period.

The following report gives the result

obtained in the treatment of a single human case:

M. D., aged 34 years, female, came to Vanderbilt Clinic on September 1, 1938, with an acute unilateral conjunctivitis of two weeks' duration, characterized by follicular and papillary hypertrophy, most marked in the conjunctiva of the lower lid. There was a swelling of the preauricular gland, pseudoptosis, and bulbar injection with edema of the limbus, but no epithelial nor other corneal changes. Cultures and scrapings revealed no significant bacteria but moderate numbers of the epithelial-cell cytoplasmic inclusion bodies characteristic of inclusion conjunctivitis. In the differential diagnosis trachoma was discarded as a possibility in view of the absence of the limbal and epithelial lesions that occur simultaneously with the conjunctival changes of this disease.

The patient was hospitalized and placed on a daily 30-grain dosage of sulfanilamide, given in three 10-grain amounts with an equal quantity of sodium bicarbonate. No local treatment was employed. Improvement was first noted on the second day, when the bulbar injection and conjunctival secretion began to diminish. Improvement continued steadily. Thirteen days after onset of therapy the eye had returned to normal except for the pres-

* From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and the Institute of Ophthalmology, Presbyterian Hospital.

ence of a tiny island of follicular hypertrophy in the outer part of the lower fornix. As a similar island of hypertrophy existed in the other eye, this condition may well have preceded the infection. Sulfanilamide was discontinued at the end of 21 days. The eye has been followed for two months after healing, and there has been no evidence of recurrence. Inclusion bodies, which averaged 15 to 25 per slide at onset of treatment, dropped to one in two slides on the second day of treatment and could not be found in examinations made every second day there-

after.**

In view of previous failures to influence inclusion conjunctivitis with local treatment of many types, this rapid response to sulfanilamide therapy is considered significant.

630 West 168th Street.

** Since this report was written, a second case, a severe bilateral inclusion blennorrhea in a newborn infant, has been successfully treated with the drug. Sulfanilamide therapy in adequate dosage over a seven-day period resulted in the disappearance of inclusion bodies (after the second day), cessation of discharge (after the fifth day), and a return to normal of the conjunctiva within two weeks.

SOME USES OF SULFANILAMIDE IN OPHTHALMOLOGY

L. PELLMAN GLOVER, M.D.
Altoona, Pennsylvania

Sulfanilamide, particularly in the form of prontosil, has proved of such exceptional value in the treatment of various eye infections that the following cases are reported. Naturally, there were some failures.

OPHTHALMIA NEONATORUM, TWO CASES

The first case in which the drug was used was in Baby F., aged seven days. A discharge had been present for three days prior to admission to the hospital on October 5, 1937. Great edema of the lids and conjunctiva was present in both eyes, with a 3-mm. perforating ulcer of the right eye. Smear showed the gonococcus in both eyes. The routine treatment for 24 hours gave no results, and, as it was feared that an ulcer would develop in the left eye, it was decided to administer prontosil. Ir-

rigations were given with saline every half hour, following which the prontosil was dropped in the eyes. Prontylin was given by mouth in milk, gr. 1, three times daily. Cold compresses were used for one-half hour on and one-half hour off. The results in 24 hours were amazing, as the eyes could be opened without effort. In three days the smears were negative. The child was discharged in 10 days with the ulcer nearly healed and the conjunctiva clear. The drops were continued in the ulcerated eye every four hours for two weeks, by which time the ulcer had flattened and was entirely healed.

Baby B., aged three weeks, was admitted on April 3, 1938, with a history of a discharge from both eyes for two weeks. Smear showed the gonococcus. This case was one of the mild forms of ophthalmia with very little edema, but a marked discharge. Treatment similar to that in the first case gave a negative smear in four days. The child was discharged on the eighth day.

ORBITAL ABSCESS, THREE CASES

Ruth J., aged eight years, was admitted to the hospital on October 19, 1937. The girl had had a cold for one week. Two days previous to admission, the left lids had begun to swell and she noticed double vision. A typical beginning orbital abscess was present with a fever of 101 degrees and 13,000 white blood cell count. A left middle turbinectomy was performed, but no pus was found. Prontosil was given intravenously, 2 c.c. three times daily, and magnesium-sulphate dressings were used on the lids. In three days all signs of trouble were gone with no diplopia. She was discharged on the fourth day.

Robert S., aged four years, was admitted to the hospital on May 16, 1938. The left eyelid had begun to swell two days previously. There was a history of chronic otitis and infected tonsils. A typical beginning abscess was present with a temperature of 102 degrees and a white blood cell count of 15,000. X-ray films showed a mass in the orbit. Prontosil, 2 c.c., three times daily intravenously, and magnesium-sulphate compresses were used. The boy was out of bed on the fourth day, acting normally, and the edema all gone.

Baby F., aged five months, was admitted to the hospital on May 19, 1938. The left eyelids had started to swell four days before, following a slight cold. On admission, marked edema was present which rapidly became worse. Since no veins could be found, prontosil was given by mouth, gr. 1, three times daily, and magnesium-sulphate compresses were used. This apparently had no benefit. The abscess was opened through the lower lid on May 22d, followed by rapid recovery. A gram-negative diplococcus was found.

CORNEAL ABSCESS, ONE CASE

Wilford S., aged five years, was admitted to the hospital on November 29,

1937. Three days before, while in a cornfield, he had fallen on a cut corn stock, striking the left eye. Nothing had been done in the way of treatment. An abscess of the cornea near the temporal limbus was present. This was 3 mm. in diameter, with bulging of Descemet's membrane present. A hypopyon half filled the anterior chamber. Prontosil was instilled every hour with atropine and cold compresses. Prontylin, gr. 2, three times daily, was given to December 4th. Typhoid vaccine, 5 million, was given intramuscularly every other day. The infection rapidly disappeared with the ulcer, and the prontosil was discontinued on December 7th. He was discharged December 11th, having only a small anterior synechia at the site of the ulcer, and the pupil well dilated.

PANOPHTHALMITIS, TWO CASES*

Samuel S., aged 72 years, was admitted to the hospital on December 2, 1937, with a typical beginning panophthalmitis, edema of the lids and conjunctiva, hypopyon, and haze of the cornea, with a small prolapse of vitreous at the 12-o'clock position. Five days before he had been discharged following an uneventful needling operation. While crossing a street, he was struck by a car so violently that the wound was opened, and evidently the vitreous was driven out. The infection followed in two days. Prontosil was given intravenously, 5 c.c., three times daily, and instilled every half hour in the eye. Cold compresses and atropine were used. The wound was cauterized with trichloroacetic acid. In 24 hours the eye was out of danger and the hypopyon gone. The treatment, along with

* Since this report was submitted a third case of panophthalmitis in a trephined eye was cured, with vision limited to light perception and projection. Another case of pneumococcic ulcer was cured, leaving only a large macula of the cornea below the pupil.

the use of typhoid vaccine intravenously, was continued for five days. He was discharged on December 9th. Vision on the eleventh was 6/12—1.

Joseph W., aged 23 years, was admitted to the hospital on April 5, 1938. That day he had been chipping stone in a barnyard. A piece of metal from the hammer pierced the center of the cornea, lodging in the vitreous. Tetanus antitoxin was given at once and cold compresses were started. In 12 hours, panophthalmitis was present. Prontosil was given at once, 5 c.c., three times daily, intravenously. This produced no results, and an evisceration was performed on the third day. Colon bacillus was found.

CHRONIC CONJUNCTIVITIS, TWO CASES

Chronic conjunctivitis is one of the most common ocular ailments seen in this locality. It usually responds quickly to simple grattage and astringent lotions. Some patients, however, drift from one physician to another without getting relief.

Mr. F., aged 39 years, a World War veteran, had been gassed. Since then he had had constant conjunctivitis of both eyes, from which he was relieved for only short periods. When first seen on January 22, 1938, he could hardly keep the eyes open and had to stop work. A severe chronic conjunctivitis, with thickening of the conjunctiva, purulent discharge, injection, and photophobia, was present. Two weeks of customary treatment gave only slight relief. A smear was then taken which showed *Staphylococcus albus*. On February 10th, prontosil was ordered, to be dropped into each eye every three hours after saline irrigations had been used. By February 25th, there was great improvement, and the treatment was reduced to thrice daily. On March 4th all treatment was stopped; the lids were thinned to practically normal thickness, and there

was no irritation. He has been doing his regular desk work, with no return of trouble for two months, the longest period of peace he has had.

Mrs. E., aged 57 years, had been treated for six months for a recurrent chronic conjunctivitis followed by a punctate keratitis. The attacks always lasted about three weeks, and atropine, among other therapy, had to be used to reduce irritation. On April 30th she developed an attack in both eyes which did not respond to treatment. On May 7th, prontosil was started every three hours, preceded by saline irrigations. On May 11th, nearly all irritation was gone and the treatment was reduced to thrice daily. By May 13th all treatment was stopped. This was the most rapid response she had ever had to any medication.

ACUTE CONJUNCTIVITIS WITH SUPERFICIAL ULCER, FOUR CASES

Mrs. Z., aged 58 years, was seen in consultation, on October 10, 1937. She was bedridden from the last stages of lymphatic leukemia. Four days previously she had developed an acute conjunctivitis in both eyes, followed by a rapidly spreading superficial ulcer. The usual care of acute conjunctivitis, combined with the use of atropine, cold compresses, and irrigations gave no relief, the ulcer having spread to about two thirds of the cornea. As the prontosil had worked so well recently in the ophthalmia case, it was thought worthy of trial. Instillations were made every hour, preceded by saline irrigations, day and night. In 24 hours the ulcer had healed about one half, and in three days epithelium had covered the whole area. The conjunctivitis disappeared in the first 24 hours also.

Mrs. R., aged 65 years, also bedridden, was seen in consultation on March 1st.

She had an acute conjunctivitis which did not respond to zinc and argyrol medication. There was a superficial ulcer about 3 mm. in diameter in the left eye, which her physician stated had been present one day. Prontosil was ordered every hour with irrigations in both eyes. In 24 hours the ulcer healed, and all treatment could be stopped in two days. She has had another attack of conjunctivitis since that time, which the prontosil corrected in one day.

Mrs. L., aged 35 years, developed an acute conjunctivitis of the left eye on May 7th, for which she used boric acid. On May 9th, she stated, pain began and when she was seen at the office on May 11th, there was marked injection of the conjunctiva with purulent discharge, and a slough of the corneal epithelium over the whole center of the cornea. Prontosil, preceded by saline irrigations, was prescribed to be administered every two hours, with cold compresses and atropine. On May 13th, there was great improvement, with only slight roughening of the epithelium, and the discharge all gone. Prontosil was reduced to administration thrice daily and the patient was discharged on the eighteenth with the cornea clear and no injection present.

Mr. E., aged 30 years, a motion-picture operator, was seen in consultation on May 21st. Four days previously he had developed an acute conjunctivitis of the left eye, for which zinc and argyrol were ordered. He continued work, but on the twentieth had such severe pain from the bright lights, that he could not continue work. When seen on May 21st, there was a slight purulent discharge, moderate conjunctival injection, and a 4-mm. ulcer of the lower cornea. Prontosil was prescribed to be administered every two hours. On May 23d, the ulcer showed only slight roughening and the patient was discharged on the twenty-fifth.

IRITIS, TWO CASES

Two cases of acute iritis were given 5 c.c. of prontosil intravenously three times daily for two days, with no results. The cases cleared up after the removal of focal infection and the use of foreign protein. The prontosil did not act as a foreign protein.

CORNEAL ULCER, TWO CASES

Mr. H., aged 65 years, a farmer, had a dislocated lens in the right eye, as the result of a blow in 1937. He had been treated elsewhere, and stated that the eye had become rapidly blind. On April 8, 1938, he was struck again in the right eye by a piece of limestone. When seen on April 11th, the eye was stony hard, with marked infection, purulent discharge, hypopyon, and a 4-mm. eroding ulcer of the center of the cornea which appeared ready to perforate. Enucleation was advised but this was refused. The cornea was cauterized with iodine and typhoid vaccine was given. On the thirteenth he was placed in the hospital, hot packs, typhoid vaccine, and protosil both intravenously and by instillation into the eye were given. Healing began at once, and the patient was discharged on the seventeenth, with instillations of prontosil ordered every three hours. He came to the office on the twenty-first, with the eye much worse, marked discharge, and great pain. He stated that he had not used the prontosil since leaving the hospital. This was started again with immediate improvement, so that by May 11th, the ulcer was nearly healed, and on the seventeenth he was discharged. A smear showed staphylococci.

Baby H., aged three months, developed pneumonia on April 29th. The family doctor stated that the left eye had become inflamed on the third day and had rapidly grown worse. The baby was ad-

mitted to the hospital on May 7th. An ulcer was present over the whole cornea which had ruptured near the limbus. A purulent discharge was present in the right eye. A smear showed pneumococci in both eyes. Prontosil was started in both eyes with saline irrigations every half hour for lack of something better. The discharge cleared up in the right eye in three days and the cornea of the left eye began healing in two weeks. After three weeks the cornea was healed leaving a large staphyloma. Possibly these eyes would have recovered with simple cleansing measures, but the disappearance of the discharge was so rapid that the prontosil probably helped.

SUMMARY

Two cases of ophthalmia neonatorum were unquestionably cured by the use of sulphanilamide directly. To see a case of ophthalmia clear up in a few days, instead of weeks, was most amazing. It is hoped that further trial will give similar results.

Two cases of early orbital abscess were cured. One case, which was seen late, was not helped. The infection was

due in this case to a gram-negative diplococcus.

One case of panophthalmitis was cured. The organism was not determined. One case was lost, the organism was the colon bacillus.

Two cases of chronic conjunctivitis were cured. The organism was the *Staphylococcus albus*.

Four cases of acute conjunctivitis with superficial ulcer were cured. No smears were taken.

Two cases of iritis were not helped.

One corneal abscess was cured.

Two cases of corneal ulcer were helped, if not cured.

Prontosil dropped in the eye did not apparently cause the least irritation in any of the cases. It appears to have a direct bactericidal action when used externally, causing a rapid disappearance, usually in three days, of the organism, particularly the gonococcus and staphylococcus.

All patients were warned not to use any type of cathartic. No ill effects were seen from the use of magnesium sulphate externally, when the sulphanilamide was given internally.

1200 Fourteenth Avenue.

SOCIETY PROCEEDINGS

Edited by DR. H. ROMMEL HILDRETH

CHICAGO OPHTHALMOLOGICAL SOCIETY

February 21, 1938

DR. THOMAS D. ALLEN, *president*

PAPILLOMATOSIS OF THE CONJUNCTIVA

DR. PHILIP A. HALPER said that his patient, a boy aged seven years, was first seen May 29, 1933, with multiple papillomata of the right lower palpebral and nasal bulbar conjunctiva, including the caruncle. The eye was irritable, reddened, and the tumors varied in size from 1 mm. to 8 mm. in diameter. The condition had been present for about a year and came on gradually following injury with an indelible pencil in the region of the caruncle. Smears showed no significant findings, and on histologic examination the papillomata showed mainly transitional cells. Wassermann reaction was negative.

On June 12, 1933, under ether anesthesia, the papillomata were removed with scissors. The conjunctiva was not excised with the tumor tissue. Following this procedure the eye was moderately reddened for a few weeks. The patient was not seen again until November, 1933, when he returned with extensive recurrence of the papillomata. At this time the tumor masses were so numerous and large that the lids could not be closed. There was extension also into the upper palpebral conjunctiva.

In May, 1934, the patient was hospitalized and under ether anesthesia the papillomata were removed. Since these tumors did not extend below the conjunctiva, it was thought best to excise each one with a fairly generous portion of its underlying conjunctiva. Each papilloma therefore was excised separately and by using a

loupe the tiniest ones measuring 0.5 to 1 mm. in diameter were removed. There was very slight postoperative reaction and the conjunctiva healed nicely. There has been no recurrence. The conjunctiva now shows only moderate scarring, and the eye otherwise is normal.

ECTOPIA LENTIS

DR. PAUL HURWITZ presented two patients of a family of three seen at Central Free Dispensary, a woman, her brother, and her son. Two others of the family had a history of verified ectopia lentis.

In all six eyes there was iridodonesis. Two pairs of pupils were elliptically shaped and eccentrically placed. In five eyes the lenses were displaced upward and nasally, the zone of internal lenticular reflection describing an arc from the 10-o'clock to the 4-o'clock position, more or less through the center of the pupillary area: there was thus an aphakic and lenticular portion of each pupil. In the sixth, the right eye of the son, the lens was only slightly displaced upward so that no aphakic portion was present. In all eyes, biomicroscopy showed a varying deficiency of zonular fibers and an irregularity of the lens margins. An alternating manifest divergence of about 40 degrees was noted in one patient.

The average uncorrected vision of each eye was 20/200, excepting that of the right eye of the son, which was 20/70. The vision of the mother could be corrected to 20/50+2: that of her brother to 20/25: and that of the son to 20/50. One patient accepted a correction of the refraction of the lenticular portion of the eye; the second accepted correction of the aphakic portion; the third, no correction without binocular diplopia. Of interest were the high myopic astigmatic skias-

copy findings of the luxated lenticular portions of the eye. In all cases there was a definite tendency toward arachnodactylia, more marked in the male members.

BILATERAL CONGENITAL MACULAR DEGENERATION

DR. MARTHA RUBIN FOLK said that the patient, C. W., aged 21 years, a white woman, was referred from the Municipal Tuberculosis Clinic where she was under treatment for bronchiectasis. There was a history of poor vision since childhood, which had grown progressively worse. The family history revealed nothing of significance. Venereal disease was denied.

Vision in the R.E. was 5/200; in the L.E., 8/200, not improved with lenses. The discs were rather hyperemic, the margins above and nasally ill defined. The retinal vessels showed marked dilatation of veins and tortuosity. In the macular region fine dark granules were grouped together closely and formed black spots irregular in shape, in size about one sixth p.d. Fine white striations radiated around the pigment zone, also a number of soft white spots and dots which were scattered throughout the periphery and about the macular region. The fields showed a 10-degree central scotoma: the peripheral fields were practically normal.

The Mantoux test gave a negative reaction; the Wassermann test a 3+ reaction. There is no history of consanguinity in the family. The Wassermann test of the mother gave a negative reaction. At present the patient is receiving injections of gold sodium thiosulphate at weekly intervals.

TREATMENT OF CONCOMITANT CONVERGENT STRABISMUS

DR. ELMER A. VORISEK read a paper on this subject which was published in this Journal (December, 1938).

THE USE OF ATROPINIZATION AND BIFOCALS IN TREATMENT OF CONCOMITANT CONVERGENT STRABISMUS

DR. GEORGE P. GUIBOR read a paper on this subject.

Discussion. Dr. Richard Gamble said that at Children's Memorial Hospital there is an unusually good opportunity to study the results of treatment of strabismus. Large numbers of cases are seen early, and on the whole they are a rather bright, coöperative group of children. Of course, in regard to occlusion, the results were not so satisfactory as might be wished, but that is universally true.

He was interested in Dr. Vorisek's figures, especially in the group of patients who had 20 degrees or less of monocular convergent squint, and who were first seen at the age of four years or less. Of this group 49 percent became straight and 25 percent became worse, whereas in the group of children four years old or older with the same degree of squint, 74 percent became straight and 7 percent became worse. This is just the opposite of what might be anticipated. He did not believe, however, that the results would have been better if treatment had been deferred until the children in the low-age group were five or six years old. He believed it wise to start treatment at the age of two or three years. It was probably true that refractions were not tested so accurately for the younger children, and perhaps the full benefit of the atropine and occlusion was not obtained. Also, some cases of alternating squint might have been included in this group. It is often difficult and sometimes impossible to be sure whether a young child has monocular or alternating squint. It is equally difficult to measure the amount of the squint angle, which may vary considerably while it is being measured.

He said that Dr. Guibor mentioned the pseudo-paralytic type of squint. This

type is interesting and quite important in that it simulates bilateral abducens paralysis, but it is really a pure type of alternating squint. It is usually seen soon after birth and the amount of squint is considerable. The child sees objects on his right side with the left eye and vice versa. So long as both eyes are open there is no need to use the external-rectus muscles. If one eye is covered it becomes necessary for the external rectus muscle to be used if the child is to see to the opposite side. Dr. Guibor did not stress the value of occlusion in this type of case as much as he himself would. The most satisfactory method is to have a baby bonnet made so that it occludes one eye and have the child wear it a few hours a day, covering first one eye, then the other.

Dr. W. F. Moncreiff, with reference to Dr. Vorisek's paper, said that it would seem rather illogical to evaluate the progress of these patients, in the sense of improvement or the reverse, on the one criterion of the size of the squint angle, when there were obviously at least two other factors of coördinate importance; namely, the state of the binocular vision, and, in the nonalternating cases, the visual acuity of the squinting eye.

By the essayist's own description of the method used for measurement or estimation of the squint angle, it could be seen that the crudity of the method would account for variations of the order which he stated were accepted as final evidence that the patient was improving or growing worse. This fact would seem to be an adequate explanation for the apparently large percentage of patients alleged to have become worse during the period of observation.

Referring to Dr. Guibor's presentation, and with reference to the cases of hyperopia combined with esotropia, it would be interesting to know how often, in the rather large material he has had the opportunity of studying, he has noted the

condition which the Germans call "Schrägschielen," in which the squinting eye has an oblique plane of rotation so that it rises above the horizontal plane when rotated to the nasal side, and sinks below the horizontal plane when rotated to the temporal side.

Dr. Roy O. Riser said that he had seen and heard parts of both these papers in preparation. Seeing the number of cases where there was no improvement and the actual number getting worse, was a matter of chagrin. One wondered why such a group of failures should exist after refraction and the amount of squint treatment that a control group gets. He wondered if it were not due in part to the fact that a certain number of children were seen who had been occluding the eye, in whom a certain improvement would be obtained both in the angle of squint and improvement of vision in the amblyopic eye up to a certain point, then continued to hold to a certain vision. Possibly the point is not sufficiently stressed, or the parents become discouraged in trying to keep a patch on, the occlusion is stopped, and when the patient returns a year or several years later the vision has again dropped. Since observing this, he had stressed the point that children who have apparently arrested improvement—still better than the first vision—should continue to occlude the better eye one full day or one afternoon a week for several years after improvement in vision has stopped, so that it will not decrease. He wondered if the cases that had not improved between the first and last refraction are not cases due to lack of persistent occlusion. If the best results obtained during the several years of active treatment were measured, the group of cases failing to show improvement would be much smaller.

Dr. Elmer A. Vorisek (closing), in reply to the question as to why some cases of strabismus became worse, said that it

was not easy to answer with much satisfaction because the underlying cause of the strabismus cannot always be obtained in very young patients. Some cases do not respond to such treatment as can be given, and if seen at the onset of the strabismus they simply progress and become worse in spite of what is called treatment.

The effect of atropine and occlusion upon amblyopia was not considered to be within the scope of this paper; however, an analysis of the data available indicates an improvement in vision in at least 15 percent. There is reason to believe that when all the records are fairly analyzed the percentage of improvement will be found to be much higher.

Twenty degrees was arbitrarily taken as a dividing line because it was felt that a convergence of this amount or less represented a moderate degree of strabismus, whereas a convergence of 25 degrees or more represented a considerable squint. The degree of binocular fusion was not reported because the entire group had not been so examined. The perimeter was used to measure the squint angle as frequently as possible, but many of the children were either too young or too uncoöperative, and the method described was found the most satisfactory in these cases.

The group herewith reported was not selected and observed for a period of years with the idea of using them for this study. They were the usual group of clinic patients. The records were taken consecutively in order to obtain an unbiased idea of the results of usual or ordinary care.

Dr. George P. Guibor (closing) said, in reply to Dr. Von der Heydt, that no operative procedure should be attempted until the patient is examined frequently and observed for six months or more, and until some form of nonsurgical treatment has been attempted. Bifocals and atropine cycloplegia especially should be used to determine their efficiency in lessening the

angle of squint and in improving the visual acuity.

Dr. Leech asked about a patient with a negligible refractive error with strabismus (one without ametropia, who converges 10 to 20 degrees): such a patient would be called a neuromuscular type in the classification used at Children's Memorial Hospital and Northwestern University. He would still use atropine in such a case to determine the efficiency in suppressing the accommodative convergence.

He thanked Dr. Moncreiff for the suggestion that the oblique plane of rotation be observed: he had seen a number of cases of cycloptropia with esotropia.

There are three types of patches used: in the first, one uses three or four layers of gauze, applied with adhesive tape; the others are made of rubber and can be attached to the lens.

Dr. Ackerman asked whether both eyes were atropinized in a patient with equal visual acuity, and in answer he said that they were. The convergence excess must be overcome as much as possible. In reply to Dr. Mayer's question, he said that for the first four months in the orthoptic clinic only occlusion was used, and the results were very discouraging. There was little improvement in the visual acuity and no improvement in deviation. However, when occlusion was used with atropine and sometimes bifocals, excellent results were obtained, especially in relieving the angle of squint.

Regarding congenital and acquired amblyopia, it is hard to differentiate between the two, although this has been done in the literature. If the patient does not improve it is usually classified as congenital: if he does improve, it is said to be the acquired ex anopsia type.

THE VALUE OF MUSCLE TESTS IN ROUTINE REFRACTION

DR. JAMES E. LEBENSOHN read a paper on this subject which was published in

this Journal (November, 1938).

Discussion. Dr. H. J. Smith wished to call attention to those patients with a refractive error which may include astigmatism. Peter has called attention to the fact that it is often unnecessary to give any vertical correction for hyperphoria: correction of the refractive error will cause the muscle imbalance to correct itself. It is not always necessary to add prisms, base up or base down, when there are lenses of unequal power. The optician may be instructed to raise or lower the optical center to give enough prism effect in the proper direction. He objected to prisms, base in, for exophoria except in older patients, and preferred to use instead exercises for convergence insufficiency arising in early presbyopia. He agreed with the speaker that the best recommendation for any refraction was the satisfied patient, no matter how it is accomplished.

Dr. J. E. Lebensohn (closing) said that Dr. Smith had offered objection to the use of prisms, base in, for convergence insufficiency. In the case cited the lenses with prisms were only prescribed for near work. The patient originally had 15 degrees of exophoria for near; after using the lenses ordered for a year, he then had 6.5 degrees of exophoria: the prisms were then reduced one half, and in the following year the exophoria for near was within normal limits, and reading glasses were prescribed without prisms. He was interested in determining the dominant eye, and any vertically acting prism prescribed is for the nondominant eye. It is surprising how much prism can be so prescribed: in one child with head tilting, 7 degrees, base up, right eye was readily accepted and relieved the condition.

Dr. Halper had objected to overcorrection of myopia at any time. Most of the patients seen were wearing an approximately correct refraction. Because of exo-

phoria still present, a little extra minus was given, and the result justified the procedure. Robert von der Heydt.

DR. CLIFFORD B. WALKER, *president*

EXPERIMENTAL IONTOPHORESIS ON RABBITS' CORNEAS

DR. S. G. SEECH opened his subject with the statement that ionic medication has been used in ophthalmology since 1900. He stated that the positive ions of zinc, copper, mercury, silver, and quinine were used for their antiseptic properties to promote healing of chronic infections and many kind of ulcers. The negative ions of chlorine, iodine, and salicylic acid were used to soften superficial scars and to promote their absorption.

He contended that the theory of ionic medication was rational, failures being due to improper technique. Imperfect penetration of ions, and formation of insoluble compounds with the plasma result in failure. The application of a galvanic current of two or three miliamperes per square centimeter of surface for a duration of two to three minutes gives the best results. The current should be gradually increased and then gradually decreased. Should the metallic part of the electrode touch any portion of the treated surface, the caustic product formed under the metal electrode will cause tissue damage.

Dr. Seech then proceeded to describe some experimental effects on the corneas of healthy rabbits. He stated that histological methods have shown that the chemical salt solution will enter corneal tissue and be disseminated through it for variable depths, and can even be extended to the posterior pole of the eyeball, in

which case permanent pathological changes result. Naturally from a therapeutic standpoint one should produce only transient changes where the tissues will return to normal after the response to stimulation. The rationale of ionic medication is to promote temporary tissue changes; upon its return to a resting state the rehabilitation of the surrounding normal tissue will commence regeneration in the adjacent diseased tissue.

In the cornea the stimulation causes fluid to be brought and interdispersed in the lamellae. The corneal corpuscles at first respond by becoming mildly edematous, and as this process continues fluid accumulation occurs in the lacunae, and there develops intercellular pressure on the individual fibers and corpuscles of the substantia propria. Repetition of the process periodically produces an alternating irritation and relaxation, which stimulates the tissues in their reparative function.

With zinc sulphate, the healing process is considerably delayed, which makes it necessary to increase the time interval between treatments, allowing sufficient time for return of the inflammatory structures to a normal state after each stimulation. A one-quarter-percent solution with one milliamper current applied for three minutes or less is satisfactory. Stronger solutions consistently induced a tendency to vacuolization in the substantia propria, even to rupture of Descemet's membrane.

Zinc chloride always produced pathological changes even in high dilution, producing marked edema, resulting in bulging of the cornea or ulceration. Hyperplasia of the epithelial elements and inflammatory infiltration of the stroma were found in these cases. On this account the agent was soon discarded.

Physiological salt solution resulted in changes so slight as to be of no therapeutic value.

Colloidal sulphur was found to be unsatisfactory, because particles of sulphur, tending to polarize, formed minute deposits of highly charged irritants in the tissue. Sections showed such peppered areas in the corneal epithelial layer.

Quinine bisulphate was borne by the tissues in concentrations as high as 10 percent for as long as a 10-minute application, with a $2\frac{1}{2}$ milliamper current. Microchemical tests were used to prove its presence in the tissues.

Dr. Seech described the changes occurring in his experiments as follows: The reparative or therapeutic change was that of a superficial reaction not extending past the anterior lamina elastica, and seen as a haziness of the cornea. This is followed by dissemination of ions in the stratified pavement epithelial layer, clinically seen as a powdery, sprayed area with hazy margins. Finally, edema of the corneal corpuscles next to Bowman's membrane which are distorted but do not lose their stellate forms.

The borderline changes Dr. Seech described as varying from mild vacuolization, tending to crush or displace the lamellae, to distortion and rupture of the corneal corpuscles, to finally marked distortion of the fibrillae with edematous fluid. The first stages are probably reclaimable.

Pathologic or destructive changes were described as a diffuse inflammatory infiltration composed of granulocytes, plasma cells, and collagenous histiocytes, all of which are later replaced by lymphocytes. Vacuolization occurs, and the cornea bulges forward. Second, inflammatory hyperplasia of the epithelium and of the posterior lamina elastica occurs. Third, dehydration and subsequent coagulation and necrosis occurs. Finally, reparative fibrosis completes the destructive change.

Dr. Seech then proceeded to describe

two cases of corneal dystrophy which he treated with quinine bisulphate iontophoresis. Both cases showed improvement after several treatments of the one-quarter-percent solution of quinine bisulphate. The first improved in vision from 20/60 to 20/20 and the second from 20/100 to 20/20.

HAROLD F. WHALMAN,
Editor.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

March 8, 1938

DR. C. H. GLOVER, *presiding*

IRIDENCELEISIS FOR GLAUCOMA

DR. E. C. ELLETT reported a case of simple glaucoma for which an iridencleisis had been performed on one eye. In this eye there was very little impairment of the central vision, but the tension was persistently around 40 mm. in spite of miotics, and there was a beginning cataract. The operation was performed a week before, with inclusion of one pillar in the wound. The healing was satisfactory and the tension 11 mm. The other eye also has glaucoma, but the field and vision are normal, and the tension is kept down with miotics. The patient is 66 years old.

In answer to a question as to the choice of operation in this case, it was determined by the fact that there is a beginning cataract and that probably some day a cataract operation will be required.

IRIDENCELEISIS FOR GLAUCOMA

DR. PHIL M. LEWIS presented a white man, aged 65 years, upon whom he had operated for glaucoma three days previously. This patient was first seen in August, 1935, and in spite of the regular use of miotics the tension continued high, O.D. 35 and O.S. 50 mm. Hg (Schiötz).

The visual fields of the right eye were moderately contracted, those of the left eye decidedly narrow. Central vision was 20/100 in each eye, unimproved by lenses. A bilateral iridencleisis had been performed three days ago. The technique was that recommended by Constantine and described by him in the *American Journal of Ophthalmology* for July, 1937.

Comment: The reason for presenting this patient was to bring to the attention of the Society the operation of iridencleisis. The writer has performed quite a number of these operations during the past three years and the results have been so satisfactory that he now prefers it to any other procedure. At first he was extremely skeptical, because he was opposed to any type of operation in which the iris was drawn into and left in the wound, but to date there have been no untoward complications.

DETACHMENT OF RETINA

DR. E. C. ELLETT presented the case of O. W., colored, aged 40 years, who had a cataract operation in 1929 on each eye, and failed to regain vision in the left eye. He had a good visual result in the right eye until July, 1937, when it suddenly failed. Examination showed almost total retinal detachment O.D., although the area up and in was barely loose and retained good color. The disc was not visible. No tear was seen. There was a good upward iris coloboma, with a dense secondary membrane, but good opening.

The outer half of the eye was exposed, the external rectus divided, and about 20 diathermy needles applied to the eye. The sclera was then trephined down and out. On November 20th the fundus was clearly seen and the whole retina reattached. The macular region shows a white scar between it and the disc. On November 6th, O.D. vision was 5/15 with +11.00 D. sph. \approx +1.00 D. cyl. ax. 150°.

HYSTERICAL AMBLYOPIA

DR. E. C. ELLETT reported the case of Sister L. B., aged 29 years, seen September 30, 1937, giving a history of convergence of the left eye and poor vision in it all of her life. There had been no other trouble until sinus disease began four years ago. After two operations on the sinuses she had double vision, relieved by another operation. In July, 1936, she got a piece of glass in the right eye, which was removed by incision. Since then she sees little more than hand motion with the right eye, at best not better than 1/60. There is no inflammation, but the left eye gives her pain. The ophthalmoscopic examination showed a normal condition: pupils equal and active. There is no organic trouble. The left eye converges 15 degrees. The fauces and conjunctiva were anesthetic. Diagnosis: hysterical amblyopia. The right-eye field was contracted to 10 degrees. Rest in bed with occlusion of both eyes for several days gave no results. It developed in conversation that she was very much concerned about the strabismic left eye and thought if it would be straightened her sight could be restored. On November 9th, a recession of the left internus was performed, and her vision was greatly improved the next day. Four days later the next test was made and her vision in both eyes was 6/6.

PODOPHYLLUM KERATITIS

DR. R. O. RYCHENER reported a case of keratitis in a chemist, aged 28 years, which followed closely the accidental instillation in the eye of powdered podophyllum. Within four hours the eye was quite painful and swollen, with acute visual failure. The appearance after 48 hours was that of a deep central keratitis with ciliary injection, and vision was reduced to 3/60. The conjunctival reaction had already receded. The corneal infiltration simulated the character of a disci-

form keratitis, but there was no staining point nor wound of entrance visible with the slitlamp. Local treatment with atropine, dionin, and hot applications was maintained for five days, during which the corneal infiltration cleared rapidly and within a week the vision was 6/6.

This was apparently a specific allergic tissue reaction to a substance which has not been previously responsible for any such reactions, for a recent bibliographic review of the ill effects produced by the dust of the root of podophyllum recorded only one such case. This was reported by Hutchinson (*Medical Times and Gazette*, 1872, v. 2, p. 516) and concerned a case of keratitis and dermatitis produced by powdered podophyllum. A recent query in the *Journal of the American Medical Association* included the report of several cases of gingivitis following the use of capsules containing podophyllum, and the answer raised the question of sensitivity of some additional medicament in the capsules. In the case here reported, no other drug was present and the powdered podophyllum was the sole causative agent in producing the reaction.

OCULAR PAIN

DR. R. O. RYCHENER reported five cases, the chief complaint of each being severe pain in the eye, the cause of each being found at a remote point outside the eyeball. Patients vary greatly in their sensibility to pain, but all these patients were at times in acute distress because of the discomfort described. This small series served to call attention to the ramifications of the sensory fibers of the fifth cranial nerve.

(1) Retained dental root and low basal metabolism. Mrs. B. W. V., aged 45 years, suffered for five years with attacks of pain and a patchy inflammation of episcleritis in the left eye, for which many examinations were made, and a cholecys-

ectomy and hysterectomy were performed without relief. She was known to have an old dental root remaining after an extraction, which her dentist had not seen fit to remove, as the X-ray examination disclosed no infection about it. Re-examination disclosed a low basal metabolism, and thyroid extract was prescribed with immediate improvement generally and marked improvement locally with no return of symptoms. Nine months later the dental root, present for seventeen years, was extracted. In the two years which have followed there had been no recurrence of the ocular pain nor of the inflammations.

(2) Dental pulp stone. Mr. W. A. B., 42 years old, suffered with attacks of lancinating pain in the left eyeball radiating supraorbitally to the parietal region, often necessitating an opiate hypodermically for relief. Numerous general and special examinations including dental and skull X-ray studies were normal. Cocainization of the sphenopalatine ganglion afforded temporary relief. Finally, due to increased sensitivity to electrical stimulation, a sound second molar tooth was extracted, which upon crushing proved to contain a pulp stone. Complete relief had continued during the ensuing eighteen months.

(3) Mucocele in lacrimal sac. Mrs. A. W. Mc., aged 48 years, complained of severe aching and shooting pain in and about the right eye and orbital region. The eye was perfectly normal in every way, but a lacrimal obstruction in the lower end of the duct caused the formation of a small mucocele in the lacrimal sac. There was no visible inflammatory reaction. Mild pressure over the sac evacuated the contents into the nose with prompt relief of the pressure symptoms

which she had related as being in the eye. Fluid could be passed through the duct without probing, and local treatment afforded continued relief.

(4) Brain abscess. A. B., 10 years old, was seen in the hospital following mastoid surgery on the right side, complaining of excruciating pain in the right eye, which would cause him to scream violently and to burrow his head in the pillow seeking relief. There was bilateral papilledema of high degree, and a diagnosis of brain abscess was made and verified by puncture and drainage. Recovery was uneventful, and pain in the eye ceased as soon as the intracranial pressure was relieved. The pain was apparently a reflex one, due to the pull on the dura about the exit of the fifth cranial nerve or its supraorbital branch.

(5) Herpes zoster ophthalmicus. Mrs. J. F. Mc., aged 68 years, was seen at home with disabling pain in and behind the left eye, already present for four days. She had been examined at one of the hospital clinics where no cause was found, and this examination showed nothing to explain the symptoms. The eye was normal to the ophthalmoscope, and there was no tenderness in or behind it on pressure, but severe pain in it persisted day and night. A general physician was called, who found the blood pressure 200/120 and an impending cerebral vascular accident was feared. Eight days after the onset of the pain, her physician reported the presence of erysipelas, which on examination proved to be typical herpes zoster ophthalmicus. Pituitrin and X-ray treatment for the pain were suggested but not used because of family prejudice to such treatment.

Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to Dr. Lawrence T. Post, 640 S. Kingshighway, Saint Louis.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver.*

Subscriptions, applications for single copies, notices of change of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 640 S. Kingshighway, Saint Louis. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the Manuscript Editor. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

SEVENTY-FIFTH ANNIVERSARY OF THE AMERICAN OPHTHAL- MOLOGICAL SOCIETY

The year 1864 marked an event of great significance in the history of ophthalmology; namely, the formation of the first society in the United States devoted exclusively to ophthalmology. It was, in fact, the first national medical organization of specialists of any kind in the United States, as far as can be learned.

The occasion is to be celebrated by a special program to which Mr. H. M. Traquair has been invited as special guest. It is interesting that on this anniversary the president should be a Canadian and the official guest an Englishman, significant of our very close relationship to our

neighbor and to our ancestral country.

Some of the early history of the society may be of interest to our readers.

Apparently the idea was first suggested in correspondence between Dr. Hasket Derby of Boston and Drs. Noyes and Bumstead of New York. This was followed by a meeting in Dr. Noyes's office at which there were present Drs. Henry B. Sands, Herman Althof, John H. Hinton, F. J. Bumstead, D. B. St. John Roosa, W. F. Holcomb, Hasket Derby, and Henry D. Noyes. Dr. Sands was elected chairman and Dr. Noyes secretary. Dr. Bumstead suggested that a committee be appointed to invite ophthalmic surgeons from the whole country to assemble in New York at the time of the

meeting of the American Medical Association to form themselves into an American Ophthalmological Association. This suggestion was adopted and Bumstead, Noyes, and Derby were appointed. A proposal to publish a journal was not accepted.

The first meeting was held on June 7, 1864, at the New York Eye Infirmary with 18 in attendance from New York, Boston, Philadelphia, and Poughkeepsie. On the first day the Constitution and By-Laws were drafted and adopted. On the next day, with Edward Delafield presiding, the first paper was read by John H. Dix of Boston on "A case of transparent neoplastic formation in the anterior chamber of an eye." Dix also read a paper on "The effect of Calabar bean upon paralysis of accommodation following diphtheria—1 case."

A publication committee of two was appointed to act with the recording secretary in publishing transactions. A list of active and honorary members was recommended. Dr. Derby exhibited a bottle containing 20 specimens of Calabar bean loaned from an exhibition by a druggist of Boston. A Committee on Publications was appointed. Bumstead and Hinton suggested that at the next meeting be presented "A report on the progress of ophthalmology during the past year." The subject for the next annual meeting was selected: "The morbid conditions functional and organic included under the name Asthenopia, their pathology and treatment."

The second meeting was held on June 13, 1865, at which 20 members were present. Dr. Jeffries of Boston made the "Report on the progress of ophthalmology during the past year," in which Donders's book on accommodation and refraction of the human eye was discussed, as well as ophthalmic photography, autophthalmoscopy, entoptics, and retinal structure.

The long bibliography attached to this report led to the motion that "a committee be appointed to be styled a 'Committee on Ophthalmic Bibliography' who shall prepare a catalogue of books, of journals, and of pamphlets relating to ophthalmology."

The only reference to the war was veiled in the last paragraph of Dr. Jeffries's report as follows: "If, during these times of excitement and anxiety, we American ophthalmologists have not perhaps contributed our share towards the advancement of our science, we shall be pardoned by our medical brethren. We have, at least, by the very formation of this Association, shown that we are anxious to learn, by mutual intercourse and interchange of thought and criticism, and that we ever have in view the one great object of our specialty, the restoration of sight."

Dr. Derby read an account of a case of "Ophthalmia intermittens" thought to be unique of its kind, beginning "Mrs. S. H., aged 59, a lady of full habit and in the enjoyment of perfect health . . ."

Dr. Bumstead offered the following resolution: "This Society shall have the prior right to publish papers read before it, and the authors of such papers shall not publish them elsewhere until after their publication in the Society's proceedings, without the consent of the Publishing Committee, or unless the Publishing Committee fail to insert them in the issue of the proceedings next following their reading; nor in any case shall papers be published as having been read before this Society without the consent of the Publishing Committee."

Dr. Dyer presented a paper, "Asthenopia not connected with hypermetropia," which was discussed at length.

Dr. Noyes read a paper on "Specialties in medicine."

The third meeting was held on June

12, 1866, in Boston with 21 members present. Dr. Henry B. Sands, of New York, read a paper on "Sudden monocular amaurosis, presenting unusual difficulties in diagnosis," the first paper to be illustrated in the Transactions, with four visual fields showing the "Limit of central obscuration" on separate dates. The fields had no axes registering degrees as at present. Another paper on the same subject was presented by Dr. Charles M. Allin (New York). Dr. Ezra Dyer, of Philadelphia, read a paper on "Fracture of the lens of one eye and of the anterior capsules of both eyes, from death by violent hanging." Results observed on this occasion led to experiments with dogs, which were violently hanged and their media observed in comparison with those of the man. An assessment for the coming year of \$10.00 was moved.

At this meeting six new active members were balloted for, among them Dr. John Green of St. Louis, who came from farthest west. The first foreigner, Dr. C. Schweigger, of Berlin, was elected honorary member.

At the fourth meeting, held at Niagara Falls, in June, 1867, Dr. Jeffries of Boston again reported on the "Progress of ophthalmology" for 1865 and 1866. In it he mentions that "the French have filled a gap in ophthalmology in their language; German investigation and study is progressing . . . rendering it all the more mortifying that there does not exist in English a complete work on diseases of the eye, brought down to the present day in ophthalmoscopy and the anomalies of accommodation and refraction; yet Mackenzie's great treatise is translated into French. . . ." The bibliography submitted contained over 50 titles, only two of which were American; namely, the "Transactions of the American Ophthalmological Society, 3d annual meeting, 1865" and H. W. Williams' "Recent ad-

vances in ophthalmic science," Boston, 1866.

A table of "Statistics of 41 ophthalmic hospitals and infirmaries" is given, the various categories including the name of the city, number of inhabitants, founded in what year, surgeons in charge, number of beds, annual number of patients (separate number of house patients), number of days of attendance, average number of days of attendance of each patient, and the important operations: cataract, artificial pupil, strabismus, and others. Five of these hospitals were in the United States—Boston 2, New York 2, Philadelphia 1—all the rest were foreign.

The record of the fifth meeting, held in Newport, Rhode Island, in July, 1868, gives for the first time the roster of members preceding the list of those present: 43 active members, 7 honorary members. Seventeen members were present.

The American Ophthalmological Society through the years has occupied a most important place in world ophthalmology. It has always been composed of outstanding men in this specialty. Obviously in a society with membership so limited that it cannot include more than approximately 5 percent of the ophthalmologists of this country there are a great many very able and distinguished names that do not appear on the roster, but there are few that have ever been there who have not been worthy. The Society has stood for the highest ideals in the profession and has been an example to other groups in its sponsorship of the best in medicine. Long may it live and prosper. The American Journal of Ophthalmology extends heartiest congratulation on this occasion.

Lawrence T. Post.

CATARACT THERAPY

Great indeed would be the jubilation if it could be proved conclusively that cata-

ract was preventable or remediable by nonsurgical procedure. Many efforts have been made to this purpose, some of them genuinely scientific, others crudely empirical. But most ophthalmologists are disposed to believe that no practical benefit has resulted from these investigations.

Medical literature presents a wealth of detail as to the chemical composition of the crystalline lens in man and other animals. Analyses have been made by Krause, Burky and Woods, Jess, and others. A number of studies deal with the immunologic properties of lens protein. The work of Duke-Elder as to the chemical composition of the aqueous humor and its relation to lens nutrition is well known. Salit has written an important series of papers as to his studies of lens composition.

It used to be thought that lens metabolism was of no importance, but a number of recent investigators have demonstrated that the lens consumes oxygen, and that the lens converts glucose into lactic acid. It has been suggested, but not definitely proved, that ascorbic acid (vitamin C) is synthesized by the lens.

As examples of recent essays on the cataract problem we may mention one by Jackson as to the causes of senile cataract (in which it is suggested that deficient hydration may contribute to the formation of lens opacities); papers by Davis and others on dinitrophenol cataract; one by Hess on the production of nutritional cataract in trout; papers by Tainter and Borley, by Derkač, and by Yudkin on the influence of vitamins; one by Givner and Gannon concerning the magnesium content of the lens; and one by Süllmann and Weekers on the origin of galactose cataract.

In addition to the lens changes associated with senescence, cataract occurs in a number of diseases of the general system, including diabetes, atrophic myotonia,

mongolian idiocy, and cretinism. It may also be produced by excessive exposure to infrared rays or by ingestion of such substances as ergot and dinitrophenol.

One of the best recent reviews of the literature concerning metabolic factors in cataract production is that of Bourne, himself a worker in this field of investigation (*Physiological Reviews*, 1937, volume 17, page 1). This author concludes that our actual knowledge of the metabolism of the normal lens is fragmentary, but that investigation of the physical chemistry and metabolism of the lens offers an interesting field for future research.

Those who contemplate devoting their time and energy to this line of experimentation may, however, do well to consider very deliberately whether they can anticipate from such research any substantial benefit to patients afflicted by cataract. In the field of prevention of those types of cataract not associated with senility, a hopeful attitude may be maintained. But, in view of the peculiar physiologic and optical qualities of the crystalline lens, a hopeful attitude seems much more difficult as regards restoration of opaque lens fibers to their normal transparency. Furthermore, the general understanding of senile changes, together with the recent investigations by Alfred Vogt as to the senescence of identical twins, seems to render particularly hopeless the problem of preventing or relieving (by other than surgical measures) those disturbances which we group under the general name of senile cataract.

At the last meeting of the German Ophthalmological Society in Heidelberg (fourth session; see summary in *Klinische Monatsblätter für Augenheilkunde*, 1938, volume 101, page 142) there were read a series of essays dealing with the composition of the lens, the causes of cataract, and the possibility of cataract

therapy. H. K. Müller denied the hopelessness of medicinal treatment, and argued that while "senile death" of the lens could not be ultimately prevented, yet some day it would be possible to find a symptomatic therapy which would influence the speed of development of lens disturbances. Rauh supported the emphasis which Siegrist has elsewhere placed upon the relation between senile cataract and disturbances of the endocrine glands. Urbanek, who had made a series of experiments as to the presence of C-avitaminosis in cataract patients, pointed out that development of cataract in old people was by no means parallel with a noteworthy deficiency in vitamin C, and urged that the relative poverty of the senile organism in vitamin C did not justify a conclusion that cataract development resulted from C-avitaminosis. Bücklers suggested that even metabolic processes, whatever significance might be attributed to them in this connection, were also controlled by the germ plasm (being therefore influenced by heredity).

Vogt, who three months before the last Heidelberg congress had published (see *American Journal of Ophthalmology*, 1938, volume 21, page 1172) what may come to be regarded as one of the classics of medical literature, his essay entitled "Further ocular studies on single-ovum twins of advanced age as to the inheritance of senile characteristics," now (*Klinische Monatsblätter für Augenheilkunde*, 1938, volume 101, page 530) takes up the cudgels against what he regards as the "guesses, hopes, and vulnerable hypotheses" put forward by various authors, especially Müller.

What, asks Vogt, are the environmental influences which Müller regards as playing a part in the development of senile cataract? Vogt's elaborate studies of identical twins disclosed no such influences. The crystalline lens of a man of eighty years may show all the normal charac-

teristics of senility, namely optical density, elasticity, color, and physiochemical composition, yet may remain perfectly clear, although on the other hand heredity may cause complete opacity of the lens at the age of thirty years.

Vogt remarks: "All the innumerable lens therapeutists of this and the previous century, who have instructed the world how to retard and arrest the development of cataract by means of iodine, injections of salt solution, ingestion of lens material, hormones, diathermy, the galvanic current, magnetism, massage, hypnotism, and so on, have without exception adapted their claims to the long established fact that most forms of cataract seem to remain stationary many years or even several decades. . . . Ordinary well water would be preferable to expensive medications."

Vogt expresses the opinion that it is useless to learn the chemistry of hereditary cataract with a view to preventing, improving, or curing it by medicinal means; just as it is useless to study, for a like purpose, the chemistry of senile graying of the hair or of nodular degeneration of the cornea or of hereditary atrophy of the optic nerve.

"Senile characteristics," he says, "are hereditary characteristics, and it is illogical to hope to avoid or correct hereditary characteristics by medicinal treatment."

As regards most discussion as to the causation of senile cataract Jackson says truly that we have "only a sort of underpinning of speculation, instead of any foundation of scientific fact, for our philosophy." But it is the firm opinion of the present commentator that this objection cannot be urged as to Vogt's work. It may even be suggested that no one who has not studied Vogt's detailed observations on identical twins has an adequate basis for conclusions as to the possibilities of cataract therapy. W. H. Crisp.

TUMORS OF THE LACRIMAL SAC

Primary tumors of the lacrimal sac are rare. The writer has seen but one (carcinoma) that seemed to have originated in the sac. When seen it had already involved the caruncle. The then new treatment with X rays (1902) caused the tumor to disappear. But deeper growths in the sac subsequently increased and involved the lacrimal bone and frontal bone. The case ended in death with cerebral symptoms. No similar case was then found in the literature, and the possibility of such tumors has rarely been mentioned in books on ophthalmology.

Penman and Wolff, in the *Lancet* for June 11, 1938, have reported a case in which the growth was excised. Its structure was shown to be that of a malignant papilloma. When first seen there was a small swelling of the sac, feeling like a cyst, and no regurgitation. Five years later the swelling was "the size of a small bantam's egg," and there was no drainage into the nose.

Swelling is often the first convincing sign of disease in the lacrimal passages, calling for surgical interference. But it is not often left to increase for five years, as in this case, and to bring complete obstruction before something is done for it. These authors, from a search of the literature, have now found records of 64 cases. Of these 24 were carcinomas, 20 sarcomas, 7 papillomas, 5 lymphomas, 4 endotheliomas, and the others benign. Tuberculosis and chronic dacryocystitis have been mentioned as causes of tumor of the lacrimal sac, but no individual case histories are reported.

It seems now established that primary tumors of the lacrimal sac occur; and the majority of them were found to have become malignant before they were removed. Failure to report single authenticated cases, and a belief that the sac is protected from many of the influences known to cause cancer elsewhere, have

led to an underestimate of the frequency and importance of such cases. Each case of the kind should be recognized, carefully studied, and reported. This will result in early and general recognition of such cases; and that is the main reliance for the control and prevention of cancer.

Edward Jackson.

BOOK NOTICES

AN EVALUATION OF VISUAL FACTORS IN READING. By Henry A. Imus, A.M., John M. Rothney, Ed.D., Robert M. Bear, Ph.D. Paper binding, 144 pages, Dartmouth College publications, Hanover, New Hampshire, 1938.

This monograph is a preliminary report on an investigation to improve the reading ability of the student body of Dartmouth College. The study was begun in January, 1936, on the freshman class, made up of 636 boys of similar age and qualifications. The Dartmouth Eye Institute made eye examinations of the entire class and errors in refraction were corrected. The eye examination also included tilting-table tests for anisiekonia and measurements of ocular movements in reading with the Ophthalm-O-Graph.

The reading ability of students in relation to education has brought forth much consideration of late. An attempt is being made on this relatively homogeneous group to find what this relationship may be and, if important, how to improve reading ability. The study includes various reading tests and methods to improve reading, in comprehension as well as speed of reading.

This study has been very comprehensive and should be of interest to ophthalmologists and educators. The group is being followed through the four years of college and additional information will follow.

Many of the conclusions are of interest to ophthalmologists. It is interesting that one third of the class had not received adequate ocular care. Ocular defects are not found most frequently among those having reading difficulties and students making low grades. The Ophthalm-O-Graph did not prove a good indicator of reading ability for this study. The extra reading program at Dartmouth is to increase the speed of reading but does not guarantee gain in comprehension in reading or improvement in college grades.

H. Rommel Hildreth.

OBITUARY

WALTER HAMILTON SNYDER

Dr. Walter Hamilton Snyder was born in Elmhurst, Pennsylvania, on September 3, 1870, of Dutch parentage; he died December 29, 1938, at his home in Toledo.

His early life was spent in Scranton, Pennsylvania, and he received his medical degree in 1891 at the University of Michigan, coming to Toledo shortly after to specialize in eye, ear, nose, and throat work. His specialized training was received at various New York and Philadelphia clinics and universities, and several European clinics, notably that of Adelbert Fuchs of Vienna.

From early in his medical career in Toledo, Dr. Snyder took an active part in the activities of the local and state medical societies, serving as councillor, and was on various committees of both organizations. In 1907 he was president of the Toledo Academy of Medicine, and in 1908 and 1909 president of the Ohio State Medical Association. In 1913 he was ap-

pointed by Governor Cox to the Board of the Ohio Commission for the Blind, and continued in this capacity until the early 1920's, when he was made president of this organization, an office he held for many years, proving himself a militant leader for reforms and benefits for the blind.

Many articles pertaining to the eye were written by Dr. Snyder, and he was frequently called upon to address the various county and city medical societies, frequently also such out-of-state organizations as the Chicago and the Detroit Ophthalmological societies. He was always alert to take advantage of new methods for diagnosis and procedure, being the first to perform the Elliott trephine operation for glaucoma in this country, one of the first ophthalmologists in this country to employ the corneal microscope, and one of the first men in Toledo to interest the local profession in the use of the X ray.

During the war he served on a Medical Advisory Committee of Local Physicians for men entering the service. He was a member of the Toledo Academy of Medicine, the Ohio State Medical Society, a Fellow of the American Medical Association, a Fellow of the American College of Surgeons, and a Fellow of the American Academy of Ophthalmology and Otolaryngology.

Dr. Snyder had a great interest in sports, being an ardent hunter and fisherman. He was especially interested in salmon fishing.

He died December 29, 1938, of chronic cardiac hypertrophy.

John D. Skow

In the December, 1938, issue, page 1397, the review of Birch-Hirschfeld's book, "Pathologic anatomy and therapy of trachoma as found in the tarsus and its conjunctiva," was erroneously credited to Dr. L. A. Julianelle. The real reviewer was Dr. Harvey D. Lamb.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is only mentioned in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. General methods of diagnosis
2. Therapeutics and operations
3. Physiologic optics, refraction, and color vision
4. Ocular movements
5. Conjunctiva
6. Cornea and sclera
7. Uveal tract, sympathetic disease, and aqueous humor
8. Glaucoma and ocular tension
9. Crystalline lens

10. Retina and vitreous
11. Optic nerve and toxic amblyopias
12. Visual tracts and centers
13. Eyeball and orbit
14. Eyelids and lacrimal apparatus
15. Tumors
16. Injuries
17. Systemic diseases and parasites
18. Hygiene, sociology, education, and history
19. Anatomy, embryology, and comparative ophthalmology

1

GENERAL METHODS OF DIAGNOSIS

Bakker, A. The sodium light in ophthalmology as an aid for unmasking malingers. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 267-272.

With the eye alleged to have suffered a diminution of vision always uncovered, the subject successively reads test types illuminated by a green and then a red light while a green and a red glass respectively are placed before the fellow eye. Finally the red glass is replaced by another red glass before the sound eye and the test types illuminated with the sodium light. Now the subject is able to distinguish letters only with the injured eye. Of course, as with all tests for malingering, both eyes must be kept open.

H. D. Lamb.

Busacca, Archimede. Research studies of the eye. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 395-405.

These technical and practical notes include principles of technique for fixing and preservation of specimens, especially Ruffini's and Bielschowsky's

methods, the removal of corneal tissue for biopsy, and the placing of landmarks on conjunctival or corneal tissue by tattooing. (Photomicrographs.)

J. Hewitt Judd.

Fink, W. H. A method for testing the visual acuity of children. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 490.

This is a modification of the "E" test.
George H. Stine.

Gassovskii, L. H. The accommodative effort in the use of visual optical apparatus. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 368.

This investigation deals with the accommodation exerted by the observer in the use of optical apparatus, which is presumably to be applied in a state of ametropia. The study shows that in focusing the ocular the observer does not always set it for his refractive error. Thus subjective determination of refraction dependent on sharp focusing of objects is unreliable. The study also shows that relaxed accommodation required for optimum working conditions with optical devices is not always at-

tained by sharp focusing of the image. The author concludes that optical instruments should have a dioptric scale, so that an observer can set the ocular for his refractive error.

Ray K. Daily.

Hildreth, H. R. Red-free illumination for Bausch and Lomb binocular ophthalmoscope. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 496.

A small air-cooled mercury arc, operating on the alternating current, is adapted to the Bausch and Lomb binocular ophthalmoscope. (Illustration.)

George H. Stine.

Klimovich, E. F., and Manshutin, M. A. Tests for the determination of visual acuity. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 382.

This is the first report of the commission to standardize visual tests. The survey of the tests in use leads the commission to conclude that the letters and signs used at present are subtended by different visual angles; that uniformity of results requires uniform conditions relative to illumination, distance, and contrast; that isolated tests afford more accurate information; and that of the tests available Landolt's ring is the best.

Ray K. Daily.

Madroskiewicz, Marion. A keratoscopic attachment for the Simon electric ophthalmoscope. *Klinika Oczna*, 1938, v. 16, pt. 4, p. 457.

The image of a semitransparent Placido disc is reflected from the ophthalmoscopic mirror on to the cornea, and is seen enlarged through a convex lens.

Ray K. Daily.

Natanson, D. M. Diagnosis of tuberculous diseases of the eye. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 209.

The diagnostic means are focal reac-

tion to tuberculin, X-ray studies of the chest, response to tuberculin therapy, culture of tubercle bacilli from blood or tissues, and typical biomicroscopic changes such as iris tubercles and characteristic corneal precipitates.

Ray K. Daily.

Paulsen and Offret. The gonorrheal complement fixation in ophthalmology. *Bull. Soc. d'Opht. de Paris*, 1937, no. 3, March, p. 157.

The test was without value in conjunctivitis, but of 84 cases of iritis it was positive in 21 per cent. Seven of the cases had definite gonorrheal foci. The test is urged as a diagnostic measure.

Harmon Brunner.

Samoilov, A. I. Focal reaction in ocular tuberculosis. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 183; and pt. 3, p. 317.

The author is a strong supporter of the use of tuberculin diagnostically to the point of focal reaction. The objective signs of a mild focal reaction should be known and recognized, and severe reactions harmful to the eye should be avoided. Among the early ophthalmoscopic signs of a focal reaction is a movement of the pigment in choroiditic foci. In exudative types of tuberculosis of the posterior ocular segment a focal reaction would be manifested by transitory increase in the retinal edema around the inflammatory foci or the disc. Excessive edema and hemorrhagic reactions should be avoided. The peripapillary edema manifests itself by enlargement of the blind spot lasting for the time of the focal reaction. Such an enlargement can be demonstrated in cases where the increase in retinal edema is too fine to be detected ophthalmoscopically. The author designates enlargement of the blind spot as the campimetric reaction.

A rise in ocular tension 2 to 2½ hours after the tuberculin injection is also a delicate objective sign of a focal reaction. The focal reaction in anterior uveitis may be exudative or hemorrhagic in type; the exudative is manifested by edema of the iris and formation of exudates in the anterior chamber; the hemorrhagic form by hemorrhages in the iris, in the perilimbal vascular network, and in the corneal tissue. These changes can be detected biomicroscopically. (Illustrations.)

Ray K. Daily.

Usefova, F. I. The focal reaction in metastatic ocular tuberculosis. *Viestnik Ophth.*, 1938, v. 13, pt. 2, p. 212.

The author demonstrates the protean manifestations of ocular tuberculosis by means of a series of clinical histories. He contends that the most important diagnostic factor is the focal reaction. This may take the form of fleeting gray tubercles on the pupillary edge of the iris, seen only with the slitlamp. The character of the focal reaction confirms the important role which the ciliary body plays in the pathogenesis of ocular tuberculosis. In disease of the retina or optic nerve the periphlebitic focus may be far in the periphery and inaccessible to ophthalmoscopy. The Mantoux reaction, indicating the degree of local allergy, is helpful in determining the dosage of tuberculin necessary to secure a focal reaction. Ray K. Daily.

Velhagen, K., Jr. X-ray diagnosis in diseases of the eye and its vicinity. *Rev. Oto-Neuro-Oft.*, 1938, v. 13, March, p. 79.

The author points out the value of X-ray diagnosis in diseases of the eye and its adnexa, and he especially emphasizes the value of such diagnosis in intracranial pathologic conditions, such

as pituitary tumor and bony deformities, which give rise to ocular manifestations. He further discusses localization of intraocular foreign bodies after the method of Comberg, the use of radiopaque substances in outlining lesions of the lacrimal apparatus, the value of the Rhese-Goalwin technique for radiography of the optic foramen, and roentgenography of sclerosed cerebral vessels in diagnosis of optic atrophy of the cavernous type without increased intraocular pressure.

Edward P. Burch.

2

THERAPEUTICS AND OPERATIONS

Berens, C. A new keratome. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 485.

This is a narrow, hollow-ground, angular keratome for paracentesis, iridocapsulotomy, and iridotomy. (Illustration.)

George H. Stine.

Busacca, Archimede. Advantages of use of coagulants in ocular operations, especially in extraction of cataract and in plastic operations. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 406-409.

The author advocates the use of coagulen, a proprietary coagulant from blood platelets. For enucleation, 20 c.c. of the coagulant is injected into the subcutaneous tissue of the abdominal wall at least two hours before the operation. For other operations the powdered form is applied locally. A dense coagulant forms, producing hemostasis. This is removed before the operation is resumed.

J. Hewitt Judd.

Coulter, J. S., and Carter, H. A. Symposium on physical therapy. Ultraviolet and infrared rays, high frequency currents. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 78.

This is a comprehensive review of the physiologic effects and application of ultraviolet, infrared, and high-frequency radiation. The authors conclude that the evaluation of methods used in physical therapy must not depend upon the opinion of the physician, but rather the facts that he can demonstrate. Until the effects of these different radiations have been critically evaluated they should be used only as adjuncts to other forms of treatment.

George H. Stine.

Desjardins, A. U. Symposium on physical therapy. The action of roentgen rays and radium on the eye and ear. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 48.

The author thoroughly discusses the experimental background and clinical radiotherapy, including indications and technique. (Extensive bibliography.)

George H. Stine.

Döhmen, Hellmuth. Bacteriologic and chemical investigations for prevention and treatment of infections of the eye. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 515.

Only in a small percentage of patients is the conjunctival sac sterile. According to frequency it contains staphylococci, streptococci, pneumococci. After experiments with different antiseptics the author found an oily mixture of ethylhydrocuprein and acridin dye superior to other disinfectants in bactericidal action. From good results in several hundreds of cases he recommends the mixture as a prophylactic against infections of the eye.

C. Zimmermann.

El-Bakly, M. A. Iridectomy technique modified to suit iridotomy cases. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 130.

The disadvantages of iridotomy operations with the Graefe knife, De Wecker scissors, and the Ziegler knife are cited, and the author outlines a technique of operation with a keratome incision which he has found useful in cases where the coloboma and pupil are obliterated. Edna M. Reynolds.

Esser, J. F. S. Rotation of the cheek in ophthalmology. *Arch. of Ophth.*, 1938, v. 20, Sept. pp. 410-416.

This plastic operation consists in rotating the loosened normal portion of the cheek combined with more or less skin of the neck for the purpose of restoring the contour of the face after all sorts of mutilation. The large incision around the cheek follows the natural lines of the face. The cheek is utilized to restore the face and the skin of the neck partly covers the cheek. This leaves a large wound in the neck instead of the original one in the face, but owing to the great elasticity of the skin of the neck the wound there can always be closed by sutures. The use of this method in four cases is reported and illustrated by photographs and drawings.

J. Hewitt Judd.

Evans, J. N. An ophthalmic carriage. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 286-289.

A portable instrument carriage is described which carries the instruments and medications for bedside dressings and examinations, charts for testing visual acuity, a hammer lamp, and, in fact, all accessories needed for a complete ophthalmoscopic examination. Photographs and a list of the 32 items of equipment carried are included in the article.

J. Hewitt Judd.

Magitot, A. Acute intolerance for atropin. *Bull. Soc. d'Opht. de Paris*, 1937, no. 3, March, p. 168.

Violent reaction occurred from one-percent atropin, so skin tests were made elsewhere on the body. Some of the tests provoked a general reaction. No reaction occurred from buccal applications. Because of the eosinophilia the author prefers the term "sensitivity" to "idiosyncrasy." Various means of desensitization were tried without avail.

Harmon Brunner.

Promptov, V. A. Substitution of naphthocaine for cocaine. *Viestnik Ophth.*, 1938, v. 13, pt. 1, p. 115.

Naphthocaine is one of the Russian preparations designed to eliminate importation of cocaine. The report of this laboratory study shows that it acts more rapidly, and withstands boiling better than cocaine; that it does not dilate the pupil, raise ocular tension, or exfoliate the corneal epithelium. It is somewhat more disagreeable than cocaine.

Ray K. Daily.

Russo, Antonio. The action of "veritol" upon the eye. *Rassegna Ital. d'Ottal.*, 1938, v. 7, May-June, pp. 328-337.

Veritol, β (p-oxyphenyl) isopropyl-methylamine is a synthetic product of the adrenalin series. It raises blood pressure and increases the hemodynamics of insufficient circulation. Beyond this the mechanism of its action is complex and not well understood. Dropped into the conjunctival sac in 3-percent solution, veritol produces mydriasis and widening of the palpebral fissure. The duration of its action is much less than that of other mydriatics, and it does not abolish the pupillary reflexes. It is well tolerated by the tissues and does not modify corneal sensibility, nor alter intraocular tension or refraction. The drug is an excitant of the sympathetic.

Eugene M. Blake.

Scheyhing, Hans. Experimental investigations as to the action of short waves on the normal and infected eyes of rabbits. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 327.

The normal eye of the rabbit is not injured by radiation with short waves at a heat tension of 17.5. Increase to 18 leads to transient opacities of the corneal surface and serious reactions in the lids. Experimental ulcers of the cornea, and suppuration in the anterior chamber caused by staphylococci, were benefited by radiation with short waves of correct dose, but abscesses of the vitreous were not influenced by such treatment.

C. Zimmermann.

Theodore, F. H. Hypersensitivity to larocaine. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 474-476.

A woman, aged 70 years, twice developed bulbar and palpebral conjunctival reactions and catarrhal corneal ulcers and infiltrates after the use of a 2-percent solution of larocaine for local anesthesia before an application of silver nitrate. A patch test on the arm gave a positive reaction. No ill effect from the drug has been reported previously.

PHYSIOLOGIC OPTICS, REFRACTION,
AND COLOR VISION

Bari, Enzo di. Consideration of near vision in the myopic eye. Graefe's Arch., 1938, v. 139, pt. 1, pp. 165-179.

The subject is treated analytically both for the reduced eye of Listing-Donders and for the schematic eye of Gullstrand. H. D. Lamb.

Ciocchi, A. Changes in the types of visual refractive errors of children. Public Health Reports, 1938, v. 53, Sept., pp. 1571-1578.

In a group of 1,481 school children, the author found that the main type of refractive error under cycloplegic, on re-examination after an average interval of almost 2½ years, remained unchanged in 75 percent of the eyes. The frequency of simple hyperopia was reduced by 20 percent while that of astigmatism (hyperopia and myopia) increased 40 percent and of simple myopia 70 percent. The chances of a change in type of refractive error appeared to decrease with age.

T. E. Sanders.

Cori, R. de. New methods for interpretation of the visual phenomenon. Graefe's Arch., 1938, v. 139, pt. 1, pp. 80-84.

With the single exception of the retinal purple in the rods, none of the theories for vision harmonizes with present histologic and microchemical knowledge of the retina. Light perception depends much more upon the light stream entering the eye, without regard to whether a larger or smaller expanse of the retina is affected by this light stream. The author cites a case in which extensive preretinal paramacular hemorrhage produced no scotoma. This

state of affairs can only be explained by the action of the horizontal and associated amacrine cells.

H. D. Lamb.

Cotlier, I. Biastigmatism of Marquez. Rev. Oto-Neuro-Oft., 1938, v. 13, Feb., p. 33.

The author describes in some detail the method of Marquez for correction of the total astigmatic error, employing bicylindric lenses. The corneal astigmatism is determined by the keratometer and the balance of the astigmatic error is uncovered by means of astigmatic dials, the total error being resolved into a single cylindric correction. (See editorials, Amer. Jour. Ophth., 1930, v. 13, p. 906; and 1931, v. 14, p. 160.) Edward P. Burch.

Eidelman, B. M. A comparison of Stilling and Ishihara plates of Soviet and foreign manufacture. Viestnik Ophth., 1938, v. 13, pt. 1, p. 124.

The investigation shows that the Kharkov edition of the isochromatic plates is as accurate as the foreign editions. Ray K. Daily.

Essen, J. The idea and significance of photic obscurity. Graefe's Arch., 1938, v. 139, pt. 1, pp. 105-117.

Obscurity means lack of optical differentiation in space. There are blind individuals whose vision is still so much a true experience that they see an obscurity. These include the psychogenically totally blind, as from hysteria. Other blind persons see nothing and also very probably recognize no ob-

scurity. In the same sense, the so-called blind spot of the eye is not truly blind. With it, obscurity is not recognized; nothing is seen. It is a true negative scotoma. All obscurity has its color, otherwise it would not be obscurity but lack of sight. There exists not only a dull black and a bright white obscurity but also a colored one. The phosphenes observed by pressure on the eyeballs with the eyelids closed are examples of this.

There are lower animals, as the worms and insects, whose only optical experience must be that of photic obscurity. The photosensitive light organs of these animals must be distinguished from the visual organs of higher sighted animals.

H. D. Lamb.

Franke, Ernst. Bodily build and refraction. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 184.

About 500 myopes, emmetropes, and hypermetropes were examined at the dispensaries of the Berlin eye clinic with regard to bodily build and growth. Among myopes leptosomatics, and among hyperopes pyknotics, were more numerous. On the average the height of the myopes was 3.3 cm. greater than that of the hyperopes. The head index in the hyperopes was higher than in the myopes. The mean values of bodily index according to Kaup and Rohrer were less in myopes than in hypermetropes. Thus the structure of the body in myopes is predominantly more slender, in hypermetropes broader. In high myopia the medium values of bodily size seems to decline, and short, heavy-set, even dysplastic types are more frequent. So-called growth myopia, mostly of low degree, appears at school age, chiefly in tall slender persons. The deleterious forms of myopia

noticeable in early youth are more frequent in individuals of short, even dysplastic bodily structure.

C. Zimmermann.

Haass, K. E. Photokinetic theory of the shadow test. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 247-266.

The author presents geometric diagrams and formulae to explain the phenomena of skiascopy. The designation of this procedure as skiascopy or the shadow test is not justified by the author. The method can correctly be designated only as photokinesis, that is, a test of the refractive condition by means of the movement of a bright field.

Hardy, L. H. A modified accommodation rule. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 493.

This is a modification of Crampton's rule, the improvements being a swivel head and three new scales. (Illustration.)

George H. Stine.

Heinsius, Ernst. Simple uncomplicated form of congenital total color-blindness. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 489.

A man of eighteen years showed uncomplicated total color blindness without impairment of vision, macular changes, photophobia, or nystagmus. Hence it is suggested that the seat of this condition is probably not in the retina but in a higher sensory center.

C. Zimmermann.

Jaeger, Ernst. Investigations on school myopia. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 205.

From 1926 to 1935 the pupils of two schools were annually examined with regard to refraction. From the twelfth year myopia very frequently began.

After the fifteenth year generally no myopia developed. Between the second and third school years myopia was found very frequently with a tendency to increase. Hence a correlation between age, bodily development, and onset of myopia was assumed, whereas no relation could be found between the mental requirements of the school and the genesis of myopia. Less favorable hygienic conditions (living, sleeping, and schoolrooms) probably promote myopia. The total results indicate that the influence of the laws of development and growth predominates over that of environment.

Malbran, J., and Adroque, E. Unilateral diplopia. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, March, p. 140.

The literature of monocular diplopia is reviewed and its methods of produc-

tion are discussed. The authors report three instances of convergent strabismus in which extrafoveal fixation had developed from abnormal retinal correspondence, binocular triplopia resulting.

Edward P. Burch.

Morawska, Maria. Skiascopically determined difference in refraction on the optic nerve and on the macula. *Klinika Oczna*, 1938, v. 16, pt. 4, p. 447.

A report of the literature and of the author's own investigations on 233 cases. Her data show an inconstant difference between the refraction of the optic disc and of the fovea. This occurs more frequently in hyperopia and astigmatism, and less frequently in myopia and emmetropia. It is independent of fundus changes and of the amount of the refractive error. In doing skiascopy it is important to skiascope the macula.

Ray K. Daily.

Paul, Ludwig. Observations on the hereditary occurrence of myopia. *Communication 1. Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 378-402.

The author reports on over 4,000 individuals belonging to 878 families. Where both parents are emmetropic, at the most only 10 percent of the first filial generation are myopic. If one parent is myopic, this percentage of myopia in the offspring increases to 30 percent, and when both parents are myopic to 60 percent. In affected families, there are about 12 percent more myopic men than myopic women among the descendants. High degrees of myopia, however, occur more often in women than in men. A sufficient number of mothers with high myopia are observed to establish that in families with highly myopic mothers, many more 'highly' myopic children occur than in families where the mothers are

emmetropic or mildly myopic, whereas a particular frequency of mild myopia in the offspring of these families does not occur.

A comparative evaluation of Stilling, Ishihara, and Rabkin plates. The conclusions are that the Stilling plates are inferior to the Ishihara and Rabkin plates, and that the Rabkin plates afford a finer differential diagnosis than the Ishihara plates.
Ray K. Daily.

Scheidt, Walter. New investigations in physiologic optics and the psychology of vision. *Graefe's Arch.*, 1938, v. 139, pt. 1, pp. 85-96.

The basis for the general principles of the neurophysiology of vision may be summarized in the synallax (associated changing) theory. This implies that the nervous system does not conduct the change (which is produced in an organ by a stimulus) but connects together several such organs and serves to balance the difference in the conditions between the affected and unaffected organs. The processes in these organs are therefore not to be considered as stimulations but as incidences (light incidence, sound incidence). The author discusses the function of the retina, the optical image in the retina, color vision, achromasia, chromanopsia, the movements of fusion and the first space dimension, the static function of the eye and the second space dimension, perception of form, the minimum visible, and the minimum separable.

Tschermak-Seysenegg, Armin. A double-slit system with wave-length constants for mixing spectral lights. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 232-246.

A double-slit system is described, as devised by the author and constructed by J. J. Fric. This apparatus insures the attainment of a pair of spectral colors which strongly maintain their average wave length in all changes either of width of slit or of intensity of the mixed color relations. To do this, on the one hand, consideration must be given to the interval between both rays in the spectrum; and on the other hand the slit width of the single slit must be the sum of the widths of both components in as wide limits as desired and continuously graduated.
H. D. Lamb.

Tschermak-Seysenegg, Armin. Observations with the neutral-light tester. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 181-231.

The neutral-light tester, devised by the author and manufactured by the Zeiss company, is described. It consists basically of a large right-angled spectroscope with a lamp producing a point of light. With this apparatus, there can be exposed to the testing lamp at one time a field with homogeneous radiation from a spectrum of a very strong dispersion, at another time (by means of an adjusting screw)

a field of undispersed light. Three spectral cardinal points (primary yellow, primary green, primary blue) are determined both by the neutral fixed eye (after exclusion of light for 3 minutes) and by the action of the light of the testing lamp. With the insertion of a double-slit system (according to Hering or Tschermak-Seysenegg), the missing primary red of the spectrum can be brought into the examination. The principles of color determination are retested and confirmed. It is demonstrated that the cardinal colors are displayed by changing the light, so that in subjective mixtures of colors all four cardinal points are deranged. In subjective primary coloring on the other hand, there follows only a displacement of both adjacent dissimilar cardinal colors, and not of the primary color concerned or of its complementary color. The tester is particularly appropriate for examination of red-green blindness.

Bielschowsky, A. Disturbances of the vertical motor muscles of the eyes. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 175-200; also *Trans. Western Ophth. Soc.*, 1938, 5th mtg; also *Acta Ophth.*, 1938, v. 16, pts. 2-3, p. 235.

The physiologic action of the vertical motor muscles is reviewed and the disturbances of these are discussed in five groups: (1) pure concomitant vertical deviations, (2) vertical deviations of parietic origin, (3) deviations that show the features of unilateral or bilateral overfunction of the inferior oblique muscle, (4) dissociated vertical deviations, and (5) vertical deviations having the combined characteristics of several of the other groups. The difficulties in differential diagnosis are outlined and illustrated by three case histories. The author warns that in cases of vertical deviations one should always bear in mind the possible complications with spastic vertical divergence innervations and should try to follow their signs in order to prevent unexpected and undesired operative results.

Bielschowsky, A. Lectures on motor anomalies. 2. The theory of hetero-

phoria. *Amer. Jour. Ophth.*, 1938, v. 21, Oct., pp. 1129-1136.

Bielschowsky, A. Lectures on motor anomalies. 3. The signs and symptoms of heterophoria. *Amer. Jour. Ophth.*, 1938, v. 21, Nov., pp. 1219-1229.

Blobner, Ferdinand. Retractory nystagmus. *Klin. M. f. Augenh.*, 1938, v. 100, Aug., p. 238.

Retractory nystagmus consists of jerky retractions of the eyeball during intentional ocular movements. They cannot be explained by pathologic changes in the orbit. According to Elschnig they are caused by diffuse pressure on the intact nuclei of the ocular muscles in the region of the aqueduct of Sylvius and their connecting fibers, and on the posterior longitudinal bundle; leading to disturbed innervation of gaze, so that in every intentional movement of gaze the voluntary impulse affects all extrinsic ocular muscles. The correctness of this localization has been proved by operative and postmortem findings. Only twelve cases have been published. The case now reported was in a man of 62 years who had been suffering for about four years from attacks of vertigo in which he fell on his occiput, with loss of consciousness and slight hemiplegia. The author assumes a traumatic genesis from hemorrhages in the region of the corpora quadrigemina. C. Zimmermann.

Frogé, Poursines, and Chiniara. Bilateral paralysis of both internal-rectus muscles, and of the iris muscles. ("Lobster eyes.") *Bull. Soc. Franç. d'Opht.*, 1937, v. 50, pp. 261-263.

The patient was a 48-year-old woman, seen four years after onset of the disease. There were spinal-fluid findings that might indicate an inflamma-

tory origin, and localization of the trouble in the course of the third nerve through the leptomeninges.

George H. Stine.

Lijo Pavia, J., and Victoria, V. Concomitant strabismus. *Rev. Oto-Neuro-Oft.*, 1938, v. 13, April, p. 95.

This article is a review of the results of tenotomy in the correction of concomitant strabismus in a series of thirty cases. The authors conclude that tenotomy alone is sufficient to achieve parallelism of the visual axes in 50 per cent of the cases, that it may be sufficient even in extreme degrees of squint, that tenotomy alone should be performed before employing other procedures, and that exophthalmos occurs in only a small percentage of tenotomized eyes. Edward P. Burch.

Marquez, M. Secondary deviation in various kinds of strabismus, especially spasmodic strabismus. *Bull. Soc. Franç. d'Ophth.*, 1937, v. 50, pp. 254-260.

The secondary deviation in the case of concomitant strabismus is equal to the primary deviation, since there is no difference in the intensity of the nervous current descending from the ocular gyrus to the two muscles. In paralytic strabismus, the secondary deviation is greater than the primary, because the nerve current must go entirely to the sound muscle corresponding with the paralyzed one, since the pathway to the paralyzed muscle is blocked. In spasmodic strabismus the secondary deviation is greater than the primary, but is less than the secondary deviation occurring in complete paralysis. Clarence W. Rainey.

Maxwell, J. T. Nature and management of the heterophorias. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 375-383.

This discussion deals with the nature and importance of tonic innervation (which is relatively stable), fusional reserve (which varies greatly not only with the condition of the general system but as a result of orthoptic training and other influences), innervation at the reading distance, management of

heterophorias by orthoptics and prisms, and measurement of convergence efficiency. Most difficulties in ocular-muscle imbalance arise from deficient positive fusional reserves at the reading distance. J. Hewitt Judd.

Ohm, J. Contribution to nystagmus. Communication 45. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 367-377.

Five new cases of total color blindness show the path of oscillation of the anterior corneal pole or of the optic nerve, when the gaze is fixed straight anteriorly, to be horizontally, slightly obliquely, diagonally circularly, or elliptically shaped. In the last the rotation may be clockwise or counterclockwise. These movements are usually different or dissociated as between fellow eyes. When looking other than straight ahead, the path of oscillation may change. The preponderant nystagmus in the color-blind and in miners is pendulum nystagmus.

H. D. Lamb.

Shaad, D. J. Binocular vision and orthoptic procedure. *Arch. of Ophth.*, 1938, v. 20, Sept., pp. 477-501.

The physiologic basis for binocular vision and the clinical diagnosis of its anomalies are briefly reviewed and the orthoptic procedures discussed in detail. The author points out the need for controlled laboratory research in this field. J. Hewitt Judd.

Travers, T. àB. Suppression of vision in squint and its association with retinal correspondence and amblyopia. *Brit. Jour. Ophth.*, 1938, v. 22, Oct., pp. 577-604.

The author discusses the subject under the following heads: the nature of suppression in squint; the color test; the mirror-screen test; suppression and

confusion; suppression in abnormal retinal correspondence; suppression, retinal correspondence, and visual acuity; the grade of binocular vision, abnormal retinal correspondence, normal and abnormal binocular vision. Methods are described and cases presented. Suppression does not always produce amblyopia. Abnormal correspondence prevents the development of amblyopia. A scheme of the development and grades of binocular vision concludes the article. The author suggests that tests such as the synoptophore method or the mirror screen are the best methods of diagnosing abnormal correspondence and measuring the angle of anomaly. (Figures, bibliography.)

5

CONJUNCTIVA

Attiah, M. A. H., and El-Tobgy, A. F. A review of the treatment of trachoma. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 97.

Various types of general and local treatment are described and evaluated. General treatment by antifollicular injections has no value and induction of general or local immunity by sera or vaccines seems of doubtful value. The only benefit in general treatment is from removal of focal sepsis.

The means of local treatment which are most useful are the salts of copper, mercury, and silver. Massage with chaulmoogra oil forms part of the routine treatment of trachoma in Egypt. It is alternated with the use of 10-percent copper sulphate. Hydnocreol and copper sulphate have the same effect as chaulmoogra oil with copper but appear to be more effective in cases where there is discharge.

Heliotherapy and electrotherapy have

been found unsatisfactory, but the use of the thermophore in pannus cases gives replacement of pannus by fine nebulae with improvement in vision. Treatment with radium is not permanent and is not superior to copper. Local ultraviolet radiation gives no better results than ordinary treatment.

Mechanical treatment is practiced as a routine. The mechanical treatment of choice is expression of follicles with Graddy's forceps. Mechanical treatment is repeated until complete scarring or cure occurs.

Edna M. Reynolds.

Benalioua. Primary tuberculous infection of the conjunctiva. *Ann. d'Ocul.*, 1938, v. 175, Oct., pp. 746-772.

Tuberculographers have long been interested in studying the portal of entry of tuberculosis, not only in the lungs, but also in the mucous membranes, skin, and conjunctiva. This paper is an extensive review of the conjunctival aspect of the problem. Primary infection by this route is relatively rare, but has been recognized in the literature since 1879. The author collected 181 cases of tuberculosis of the conjunctiva, 62 being apparently primary lesions, and nearly all in children or young women. At the site of inoculation a subacute conjunctivitis develops, with minimal symptoms but an accompanying adenopathy. The conjunctivitis may be nodular, ulcerative, vegetative, or pseudomembranous. The preauricular gland becomes swollen and often caseous. Later the glands of the neck are involved. In the early cases there is no evidence of systemic tuberculosis and the tuberculin test is negative. Diagnosis rests on recovery of the tubercle bacillus from the conjunctiva and exclusion of syphilis, soft chancre, glanders, tularemia, and sporotrichosis.

In spite of general opinion, the prognosis is really fairly good. Mild and expectant local treatment should be accompanied by general measures. (Extensive bibliography.)

John M. McLean.

Bietti, Giambattista. Melanotic conjunctival concretions after prolonged instillation of adrenalin. *Boll. d'Ocul.*, 1938, v. 17, Feb., pp. 65-79.

The writer reports two cases. A man of 29 years, affected by spring catarrh, had instilled adrenalin in both eyes six or seven times a day for the preceding seven years. A woman of 32 years, also affected by spring catarrh, had instilled adrenalin in the left eye every hour for seven months. In each case the palpebral and bulbar conjunctiva showed numerous black granules which upon histologic examination proved to be conjunctival concretions of the type found in chronic conjunctivitis. In these the melanin was deposited. (Bibliography, 8 figures.)

Melchior Lombardo.

Borsello, G. Anatomical pathology of the trachoma granule. *Rassegna Ital. d'Ottal.*, 1938, v. 7, May-June, pp. 361-407.

Borsello presents an extensive bibliographic review and describes the pathologic anatomy of the various elements which constitute the trachoma nodule. He concludes that one must admit the prolonged action of a stimulus by an unknown agent, or by a toxin of its production, in which the conjunctival tissues react with hyperplasia of their lymphatic components. A clear expression of this hyperplasia is the formation of nodules, with follicles secondarily activated, of histiocytic nature. The morphologic picture, the evolution, and the decline of this hyper-

plastic formation lead one to assign to it an inflammatory character and the significance of a granuloma. (12 figures.)

Claessen, Leontine. A case of simulation. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 27.

A little girl simulated conjunctivitis on several occasions. Ultimately a few orange pips were discovered in the lower cul-de-sac. The motive was uncertain.

J. B. Thomas.

Cossu, Giovanni. Acute conjunctivitis caused by micrococcus catarrhalis. *Rassegna Ital. d'Ottal.*, 1938, v. 7, May-June, pp. 351-360.

Cossu describes the morphologic, cultural, and biochemical characteristics of micrococcus catarrhalis, the gonococcus, and the meningococcus, and their differentiation. He describes three cases personally observed and concludes that the following changes are characteristic of this infection: tumefaction of the lids, more or less pronounced, with lid margins covered by yellowish crusts; the palpebral conjunctiva always reddened and swollen, with frequently a velvety appearance and at times covered by a pseudomembrane easily removed; abundant yellowish secretion; cornea never involved. Recovery occurs within a few days and is hastened by argyrol and later zinc-sulphate drops. Routine examination of the secretion in all cases of conjunctivitis is urged.

Eugene M. Blake.

Derkač, V. Antimony in trachoma. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 418.

The author had such good results from intravenous injections of one-percent antimony in trachomatous pannus that he uses the treatment regularly in his practice. The Weil-Félix reaction became negative after treatment with antimony. Like results followed injections of antimony-Fuadin and neostibosan. The method is contraindicated in patients with a tendency to lung affections, because it causes an irritating cough. C. Zimmermann.

Derkač, V. The question of rickettsias in trachoma. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 247.

Recent tests by Pöstić of 100 trachoma patients with the Weil-Félix reaction confirm the results reported by Derkač (see *Amer. Jour. Ophth.*, 1938, v. 21, p. 464). Further observations lead the author to the probable conclusion that trachoma is a rickettsia disease, as argued by Busacca, Cuénod and Nataf, and others. The impression that the trachoma rickettsias are related to those of typhus fever, is confirmed by the positive Weil-Félix reaction. There are several groups of trachoma rickettsias, and perhaps each endemic area has a different variety, each giving a different titer of agglutination. Trachoma is propagated from man to man directly through rickettsias contained in tears, and indirectly by transmission through infected lice. People afflicted with lice infect their eyes by rubbing them with fingers contaminated by the feces of lice in which rickettsias are contained. Local rickettsiosis must be distinguished from general rickettsiosis. Trachoma is local rickettsiosis which may occur without the agency of lice. General rickettsiosis gives a positive Weil-Félix reaction, is produced by infection from louse bites, and may thus occur in healthy nontrachomatous per-

sons. Pannus is a symptom of general rickettsiosis. In 95 percent of the cases it appears after antimony injections. A combat against endemic trachoma calls for complete freeing of the infected district from lice as a prerequisite.

C. Zimmermann.

Dudinov, S. A., and Zepenuk, L. M. Changes in refraction following excision of pterygium. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 100.

A tabulated report of the changes in 21 patients. The conclusion is that pterygium reduces visual acuity by causing horizontal flattening of the cornea. Surgical removal of the pterygium is followed by improvement in visual acuity. (Illustrations.)

Friede, Reinhard. Conjunctival graft of the entire conjunctival sac with insertion of a glass shell in total symblepharon as the result of chronic pemphigus. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 323-324.

In the case of a 67-year-old man with bilateral total symblepharon and corneae cicatrized, dry, and opaque from pemphigus, the entire conjunctival sacs from both eyes were excised. In two halves, the excised normal conjunctival sac from each eye of a cadaver was placed on a symblepharon shell and inserted into position. The larger part of the graft sloughed. After two months, the cornea in the left eye ulcerated and exenteration of the eyeball was performed. In the right eye, the conjunctival sac, after the symblepharon shell had been left in place for three months, began to shrink and dry and total symblepharon gradually recurred.

Goldfeder, A. E., and Viner, K. G. The role of latent malaria in trachoma. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 87.

The authors urge antimalarial therapy in cases of trachoma with clinical malaria, in cases with a history of malaria, and in cases in which the corneal complications appear out of proportion to the lid involvement and the usual therapy is ineffective.

Ray K. Daily.

Grancini, L. E. Oriel's substance "P" and spring conjunctivitis. *Boll. d'Ocul.*, 1938, v. 17, Jan., pp. 27-39.

Oriel, studying in 1929 the metabolism of proteid substances in patients affected by allergy, isolated from

the urine a substance he indicated with the letter "P." This substance, inoculated in other persons, reproduced the allergic syndrome presented by the patient, but the syndrome was not manifested if the same patient was injected with substance "P" obtained from another patient affected by a different form of allergy. The specific substance appeared in the urine only during the allergic attack. In tabulated form the writer gives the results obtained by treating with such specific substances fourteen patients affected by spring conjunctivitis. He concludes that this type of conjunctivitis is an anaphylactic disorder. The results were satisfactory as to subjective but negative as to objective symptoms. (Bibliography.)

Melchior Lombardo.

Hurst, V. R. Conjunctival granuloma with adenopathy. *Texas State Jour. Med.*, 1938, v. 33, March, p. 760.

Hurst saw nineteen patients with oculoglandular syndromes. Sections of tissue were sent to six ophthalmologists, who disagreed as to diagnosis of the basic pathology. A case in a 17-year-old boy is reported.

Pascheff, C. The origin of folliculoma and follicles in Denig's transplant. *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 361.

Pascheff's earlier researches showed that trachoma was not an exudative but a hyperplastic process, with confluence of follicles. This he termed folliculoma in place of the usual designation of granulations or granuloma for the conjunctiva and pannus crassus or sarcomatosus for the cornea. A new observation of an incipient confluent pannus follicularis or folliculoma of the cornea, with evolution of follicles to folliculoma, is reported, and also a relapse of follicles in transplanted oral mucous membrane after excision. The follicles always originate around the blood vessels, and the folliculoma is the final product of this development.

C. Zimmermann.

Poleff, L. Seroreaction of Weil-Félix in trachoma. *Klin. M. f. Augenh.*, 1938, v. 101, Aug., p. 243.

According to most authors the rickettsias make up the trachoma inclusions (Prowazek and Halberstädter) which were formerly interpreted as elementary corpuscles. By cultivation of trachomatous tissue Poleff confirms the belief that these formations are living organisms. The positive Weil-Félix reaction obtained by the author in trachoma speaks for the rickettsia nature of the pathogenic agent of that disease.

Thygeson, Phillips. Mannitol fermentation as an indicator of conjunctival pathogenicity of staphylococci. *Arch. of Ophth.*, 1938, v. 20, Aug., pp. 274-275.

The manitol fermentation test as performed on phenol red-mannitol agar plates is a reliable indicator of the probable conjunctival pathogenicity of staphylococci. J. Hewitt Judd.

Tichvinskii, B. T. The use of egg membrane in plastic operations on the eyeball. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 397. (See Section 16, Injuries.)

Trapezontzeva, E. E. Rickettsia in trachoma. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 378.

As a result of her investigations Trapezontzeva concludes that ricket-

tsia, found in the intestines of lice infected with trachoma, are not the causative agent of trachoma. The presence of rickettsia is incidental and can be avoided by careful laboratory technique, and they are to be regarded as non-pathogenic parasites of lice.

Ray K. Daily.

Wilson, R. P. The pathology of trachoma. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 1.

In Egypt, trachoma usually commences with an attack of acute ophthalmia. The very first changes are those of subacute inflammation in the palpebral conjunctiva, and smears at this stage commonly show intracellular inclusion bodies. In the early stages of trachoma-follicle formation, there is no feature or characteristic cell whereby it may be distinguished from a follicle of simple origin. Egyptian trachoma is characterized by a marked tendency to spontaneous cicatrization. The pathology of trachoma is simply the pathology of chronic inflammation.

The author is definitely not of the opinion that the trachomatous changes in the limbus and cornea are due to extension by way of the fornix and bulbar conjunctiva, but thinks that the corneal changes occur as the direct result of infection by contact with the lid.

Khavina, A. O. Intravenous administration of magnesium sulphate in the treatment of corneal ulcers. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 254.

The author finds the dehydrating influence of intravenous injections of magnesium sulphate very effective in the treatment of corneal ulcers.

Ray K. Daily.

Kleefeld, G. Treatment of herpetic affections of the cornea and of dendritic ulcer by sulfanilamide derivatives. *Bull. Soc. Belge d'Opht.*, 1938, no. 76, p. 14.

Kleefeld reports results obtained by treatment with sulfanilamide derivatives, astreptine (Meurice) and white prontosil (Bayer) in twenty cases of herpes of the cornea and five cases of dendritic ulcer. A brief history of each case is included. The treatment was in general limited to ingestion of the medicine without local treatment. In the majority of cases a cure resulted, but relapses were observed even during treatment. No serious incidents occurred. The writer concludes that sulfanilamide derivatives act upon diseases due to a virus. Also that they can cure corneal herpes, superficial punctate keratitis, and dendritic keratitis. However, the limited number of cases does not warrant the conclusion that cures will be permanent, and some cases, especially chronic ones, are not affected by the treatment. Only future research can safely indicate what preparation of sulfanilamide should be chosen, as well as the dose and the duration of treatment.

J. B. Thomas.

Moretti, Egisto. Contribution to the surgery of trachomatous corneal pannus. (Perirrhaphy.) *Klin. M. f. Augenh.*, 1938, v. 101, Sept., p. 373.

Moretti rejects the traumatic genesis of pannus by friction with the trachomatous tarsal conjunctiva; and he discusses the drawbacks of peridectomy, often leading to symblepharon. In 1929 he devised the limborrhaphy, which in every case improved sight with complete resorption of pannus. Observation of a large number of patients with good results has convinced him that interruption of the vascular net of the pannus is not absolutely necessary for success, which is rather to be attributed to the hyperemia produced by the remaining catgut thread. Hence he has abandoned peridectomy, and uses a technique which exerts stronger irritation of longer duration. He calls the method perirrhaphy. Three mm. from the cornea a thread of black silk is carried along the whole periphery of the cornea, reinserting the needle from point to point to form an episcleral ring. The ends of the thread are left long and are carried out at the lateral angle. This creates an intense but harmless hyperemia, capable of increasing the phagocytic elements in the cornea, leading to absorption of the pannus newformation and healing of corneal ulcers. The thread may remain from 20 to 30 days. C. Zimmermann.

Motolese, Alfonso. Epithelial and endothelial dystrophies of the cornea. *Boll. d'Ocul.*, 1938, v. 17, Jan., pp. 1-13.

In a man of 34 years, slowly progressive bilateral endothelial dystrophy of the cornea was followed by epithelial dystrophy. The patient, whose father was luetic, was the only one of five children who was affected by eye disease.

One had died of tuberculosis, and the patient was affected by tuberculosis of the lungs. Two sisters, 14 and 24 years of age respectively, each showed a congenital affection of the cornea, with typical signs of Fuchs's epithelial dystrophy of the cornea. (1 figure.)

Melchior Lombardo.

Oradovskaja, E. I. Campimetric focal reactions in the diagnosis of tuberculous choroiditis. *Viestnik Ophth.*, 1938, v. 13, pt. 2, p. 199.

On the basis of 29 clinical cases the author concludes that the reaction of choroidal foci to subcutaneous introduction of minimal doses of tuberculin is always an enlargement of the blind spot. This enlargement appears 24 hours after the injection, may last and increase for 48 hours, and then gradually recedes. The extent of the enlargement depends on the dose of tuberculin and on the sensitivity and character of the choroiditic focus. The enlargement of the blind spot can be demonstrated in cases in which ophthalmoscopic changes cannot be detected and is the result of edema of the optic nerve and adjacent retina. This enlargement is always absent in healthy eyes. The reaction is a very valuable diagnostic sign, more sensitive than the ophthalmoscopic or tonometric findings.

UVEAL TRACT, SYMPATHETIC DISEASE AND AQUEOUS HUMOR

Bakker, A. Some noteworthy movements of the pupil. *Graefe's Arch.*, 1938, v. 139, pt. 2, pp. 273-279.

It was found by experiments with rabbit's iris, transplanted to a culture fluid, that fresh amounts of acetylcholin were produced for several days. The concentration of acetylcholin may be so great that the pupillary contraction caused by its strong irritation of the oculomotor fibers is not overcome by atropine. Contraction of the pupil with paracentesis when previously dilated by atropine is explained by the strong irritation of the oculomotor fibers due to change in intraocular tension.

H. D. Lamb.

Baquis, Mario. Ocular complications of intestinal amebiasis. *Rassegna Ital. d'Ottal.*, 1938, v. 7, May-June, pp. 338-350.

In about 50 percent of the cases of intestinal amebiasis there are ocular complications, and in the majority of these the anterior uveal tract is involved. Of 108 cases in the literature only three showed involvement of the choroid. Baquis adds another case to this list—a soldier of 31 years with amebic enterocolitis. The patient developed bilateral choroiditis, more marked in the left eye. Three hypotheses as to the relation between the ocular pathology and the intestinal disease are presented: (a) direct invasion of the blood stream by amebae, (b) bacterial invasion through intestinal ulceration, and (c) toxins from the amebae. The author inclines to the last view. All other causes of choroiditis were carefully excluded by a two-year study of the patients.

Eugene M. Blake.

El Bakly, M. A. A peculiar case of polycoria. *Bull. Ophth. Soc. Egypt*, 1936, v. 29, p. 153.

Supernumerary pupils exactly in the horizontal meridian and in the outer half of each iris are described. The

openings were lined with iris pigment and reacted to light simultaneously with the pupil. In the right eye a ridge of iris tissue was adherent to the cornea near the limbus.

The literature on congenital anomalies of this sort is briefly reviewed, as well as the embryology of the anterior chamber. Edna M. Reynolds.

Farina, Ferdinando. Tuberculosis, syphilis, and chronic anterior uveitis. *Rassegna Ital. d'Ottal.*, 1938, v. 7, May-June, pp. 301-327.

Farina studied forty cases of chronic anterior uveitis with the greatest minuteness, including microscopic examination of the aqueous. He relates four cases in detail, as typical of the group, and concludes that if one excludes the cases that are obviously associated with definite etiology, such as focal infection or recurrent fever, and also those associated with active syphilis or tuberculosis, one will find a latent luetic or tuberculous basis for the remainder. In the cases commonly ascribed to rheumatism, endocrine disturbance, or intestinal stasis, and so often resistant to treatment and subject to recurrence, he believes that syphilis and tuberculosis are underlying causes and that treatment should be on this basis. Study of the cells in the aqueous supports this contention as do also the serum reaction and tuberculin tests.

Eugene M. Blake.

Fleischanderl, A. Concerning the clinical course and pathology of spontaneous choroiditis. *Wiener klin. Woch.*, 1938, v. 51, Oct. 7, pp. 1096-1099.

A male patient aged 27 years had noted diminished right vision during the two weeks prior to his first examination. Examination revealed the

picture of occlusion of the central vein and masses of exudate over the upper half of the optic disc. In the left eye, whose vision was normal, there was an apparently old disseminated chorioretinitis. During the following three months, increase of right intraocular tension necessitated several operations, but the eye remained hard, and right vision was completely lost, although the inflammatory symptoms gradually subsided and the eye became pale. Tuberculin therapy. Three years afterward renewed attacks of pain necessitated enucleation of the right eye.

Histologic examination of the globe revealed, in addition to the residua of the first exudative inflammatory attack around the optic nerve, an extensive infiltration of the choroid with nodules composed mainly of epithelioid cells, that is, the typical picture of a chronic infiltrative process. The author's findings confirm Meller's statement that infiltration with epithelioid cells is the outstanding feature in the histologic picture of this disease. This case also illustrates well the fact that spontaneous choroiditis may manifest itself under different clinical and pathologic pictures, even in the same eye, combining not infrequently acute exudative and chronic infiltrative processes. Although search for tubercle bacilli was negative in this particular eye the author feels no doubt about the tuberculous nature of the affection. Bertha A. Klien.

Gallino, J. A. Free cyst in the anterior chamber. *Trabalhos do Primeiro Cong. Brasileiro de Ophth.*, 1936, v. 1, pp. 305-310.

A young man 19 years of age showed a small oval cyst about 1 by 2 mm., lying in the iridocorneal angle at the 6-o'clock position. The thin membranous wall of the cyst showed pigment

deposits of the color of the iris. The cyst was free and moved in different directions with movements of the patient's head. The rest of the eye, as well as the vision, was found normal. The pathogenesis is briefly discussed. The author is inclined to believe that the cyst originated in proliferation of epithelial cells on the surface of the iris or ciliary body, these cells undergoing cystic degeneration and becoming detached by some slight trauma.

Ramon Castroviejo.

Grolman, G. von. Recent observations on central serous chorioretinitis. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, May, p. 235.

The author's attention was first drawn to this condition by the work of Asayama, who described a type of central serous chorioretinitis characterized clinically by a grayish-white edema confined to the macular region. The edema is sharply localized and is due to a serous exudate between the choroid and retina. Occasionally tiny hemorrhages are found. Subjectively there is a diminution of visual acuity, with a central scotoma corresponding exactly to the area of retinal disturbance. Micropsia and disturbances of light and color sense may be present. The condition lasts from one to eight weeks and the prognosis is favorable in the majority of cases. Tuberculous etiology can be demonstrated in most cases. This type of chorioretinitis may be confused with retrobulbar neuritis, and the diagnosis is greatly facilitated if the fundus is examined with the binocular ophthalmoscope. Three cases are reported in detail. (Illustrated.)

Edward P. Burch.

Guillaumat, L. Ocular complications of the icterohemorrhagic spirochete.

Arch. d'Ophth. etc., 1938, v. 2, Sept., p. 785.

The case of a young man whose left eye presented an iridocyclitis with optic neuritis consecutive to an infectious relapsing jaundice is reported. The blood test for the spirochete of Inada-Ido was positive. Five months after onset, and after repeated attacks, the eye quieted and the vision improved. Rubiazol by mouth was credited with the cure. The spirochete and the pathogenesis of the disease are described, and a discussion of the literature follows. (Bibliography.) Derrick Vail.

Gutzeit, R. Remarks on the article "Color of eye" by H. Stockmann. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 565.

Stockmann's assertion that the number of individuals with brown eyes above the 55th year of life solely depends on the progressive discoloration of the iris in senescence (see *Amer. Jour. Ophth.*, 1938, v. 21, p. 1054) is not correct. The color proportion depends (apart from senile discoloration of the iris) essentially upon the population in which the number of brown-eyed is ascertained.

C. Zimmermann.

Kronfeld, P. C., and Lin, C. K. Further studies on the regeneration of the aqueous in man. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 262.

The authors performed more than 200 anterior-chamber punctures for diagnosis and treatment. They conclude that the intraocular tension of the human eye immediately after paracentesis depends upon the relation between the volume of the anterior chamber and the volume of the entire globe. The time necessary for restoration of intraocular

pressure to the original level depends on the original volume of the anterior chamber, while the rate at which new intraocular fluid is formed appears to be independent of the original chamber volume. Complete emptying of the chamber is a stronger stimulus than partial emptying as far as the reactive changes such as hypertension are concerned. (Bibliography, discussion, 4 tables.) George H. Stine.

Mieses-Reif, Maria. The pigment content of the hair and the iris. *Klinika Oczna*, 1938, v. 16, pt. 4, p. 460. (See *Amer. Jour. Ophth.*, 1937, v. 20, June, p. 657.)

Pautrier, L. M. The ocular lesions of Besnier-Boeck-Schaumann disease. *Arch. d'Ophth. etc.*, 1938, v. 2, Aug., p. 689.

A biopsy from the skin lesions of a case of Heerfordt's syndrome (parotiditis, facial paralysis, iridocyclitis with visual disturbance) showed the characteristic structure of Besnier-Boeck-Schaumann disease (sarcoid or benign lymphogranulomatosis). Animal-inoculation experiments showed no tuberculosis, and for that reason the author believes that a virus not as yet isolated is responsible. Evidence is presented that Heerfordt's syndrome is but a part of the picture of Boeck's disease. Derrick Vail.

Uebe, Vera. Malformations of the iris. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 586.

Included are: two cases of aniridia with opacities of the lens, nystagmus, and glaucoma; a case of superficial iris coloboma and connections of the iris with the posterior surface of the cornea (mesodermal dysgenesis); a case of

ectopia of the pupil on both sides, with gaps in one iris; a case of extensive connections between the anterior layer of iris and the cornea, the iris being split into two layers; a case of embryotoxon corneae posterius, with filamentous adhesions to the iris, and glaucoma; two cases showing extensive remnants of pupillary membrane, exudations in the vitreous, and lens opacities; and two cases showing nodular protrusions of iris stroma, explained as intraepithelial iris cysts.

C. Zimmermann.

Viallefont and Lafon. Entopic pupillometry: spontaneous variations of pupillary diameter. *Arch. d'Ophth. etc.*, 1938, v. 2, Nov., p. 991.

A light source placed behind and to the side of the observer is reflected into the pupil by a brightly polished convex surface (metal button) held 1 cm. from the side of the eye. A luminous circle is thus projected against the Bjerrum screen one meter away. By this means spontaneous variations in pupillary diameter were studied. Movements of dilatation are slow and are apt to be unperceived. Movements of contraction are rapid. No regular rhythm was found, and the movements are independent of blood circulation, respiration, or psychic phenomena. (Diagram.) Derrick Vail.

Weekers, L., and Reginster, H. A new syndrome; iritis, acute ulcers of the mouth and vulva. Its relationship to relapsing hypopyon iritis. *Arch. d'Ophth. etc.*, 1938, v. 2, Aug., p. 697.

The dermatologists have recently drawn attention to a relapsing syndrome peculiar to the female, consisting of thrush of the mouth, acute ulcers of the vulva, and iritis. Relapsing hypopyon iritis in the male has been known

for some time. The authors believe that the disease is the same in both sexes, and propose that it be named "allergic relapsing hypopyon uveitis." Sulphanilamide treatment yielded a very favorable result in one of the cases reported. Blood transfusions are also advised. (Bibliography.) Derrick Vail.

GLAUCOMA AND OCULAR TENSION

Archangelskii, P. F. *Biomicroscopy of the cicatrix following Elliot's operation.* *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 21.

The arrangement of blood vessels around 24 postoperative cicatrices was studied. The author finds that the blood-vessel arrangement is very similar to that enclosing a foreign body or surrounding a corneal infiltrate. He attributes the reduction in tension following successful operation to increased drainage through the blood vessels surrounding the cicatrix. Ray K. Daily.

Cornet, Emmanuel. *Cyclodialysis sclerectomies.* *Ann. d'Ocul.*, 1938, v. 175, Sept., pp. 678-686.

The author combines Lagrange's sclerectomy and Heine's cyclodialysis. There are two types of operation, the anterior or limbal, and the posterior or retrociliary. In the first, a Lagrange sclerectomy with peripheral iridectomy is accompanied by cyclodialysis from the limbus posteriorly. In the second, a Heine cyclodialysis is accompanied by posterior sclerectomy at the site of the usual cyclodialysis incision. Seven rabbits were operated on by the new techniques. Four survived operation and had slightly subnormal intraocular pressure for weeks afterward.

John M. McLean.

Friemann. The action of veritol on the human eye. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 583.

Veritol, a preparation similar to adrenalin, was entirely satisfactory in glaucoma for lowering intraocular tension, especially when the usual drugs did not bring the tension to normal.

C. Zimmermann.

Gilde, Irmgard. Investigations on the action of pilocarpine, homatropine, and coffee on the intraocular tension of the normal eye as basis for diagnosis of latent glaucoma. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 586.

Homatropine and coffee produced a slight increase, pilocarpine in a third of the cases a decrease after moderate initial increase. In these experiments the normal eye showed fluctuations of pressure as in glaucoma.

C. Zimmermann.

Kovarskaja, S. S., and Krol, A. G. Disseminated subcapsular glaucomatous cataract. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 262. (See Section 9, Crystalline lens.)

Mikhailova, E. V. The median blood pressure in glaucoma. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 78.

The median blood pressure of 34 glaucoma patients was determined with the oscillometer. The findings show increased pressure in 75 percent of the cases. Increased median pressure without a rise in systolic pressure was found in 37.5 percent, and a rise in both pressures in 37.5 percent.

Ray K. Daily.

Ratinova, K. A. Comparative evaluation of the effect of pilocarpine and eserine on the scotoma of the glaucomatous eye. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 237.

Samoilov proposed the pilocarpine diagnostic test to differentiate glaucomatous scotomata from scotomata of other etiology. He maintained that in glaucoma pilocarpine causes a shrinking of the blind spot, while in other diseases the instillation of pilocarpine has no effect on the size of the blind spot. The author's present investigations were concerned with determining the relative value of pilocarpine and eserine in this test. The results show that both eserine and pilocarpine produce a temporary shrinking of the blind spot. Two percent pilocarpine produces greater contraction than 0.25 percent eserine and is therefore preferable for the test. The duration of contraction of the blind spot may be used to determine the frequency of miotic instillation necessary in the treatment of glaucoma.

Ray K. Daily.

Robertson, J. D. Intraocular pressure in nephrotic edema. *Lancet*, 1938, v. 234, June 25, pp. 1435-1436.

The intraocular pressure was measured in a series of cases of marked nephrotic edema and found to be within normal limits. As the plasma proteins rose the edema subsided, but no change took place in the level of the intraocular pressure. The eye, therefore, does not share in the water-logging common to other tissues of the body, and is unaffected by failure of the factors which govern the normal interchange of fluids throughout the body. These observations suggest that the aqueous humor can no longer be regarded as a dialysate.

T. E. Sanders.

Rokitzkaia, L. V. Clinical studies of the ocular reaction on the fellow eye. *Viestnik Ophth.*, 1938, v. 13, pt. 3, p. 337.

A review of the literature and a study

of 40 operative cases of primary glaucoma, 19 cataract cases, and 13 enucleations. The conclusions are that changes in the ocular tension of the non-operated eye confirm the interrelation of the processes in the two eyes. These changes are most pronounced in glaucoma. They are transitory, and no definitely permanent changes could be demonstrated. No relation could be demonstrated in the degree of reaction to the type of pathologic process or the effectiveness of the operative procedure. The appearance of variations in the ocular tension of the fellow eye prior to the operation suggests a psychogenic origin rather than a pain reflex. An effect on the ophthalmotonus of the good eye was found also after akinesia; which shows that action on the eyeball itself is not essential for this reaction. The latter is probably the expression of a series of complicated processes acting on the patient. The absence of any regularity in these changes is probably due to individual variations in the nervous system.

Ray K. Daily.

Satanowsky. Paulina. Treatment of absolute and painful glaucoma by X rays. *Arch. de Oft de Buenos Aires*, 1938, v. 13, May, p. 227.

In painful, blind, glaucomatous eyes the use of X rays for relief of pain is advocated. It is claimed that the majority of eyes so treated are rendered free from pain even though the intraocular tension remains elevated. Glaucoma following central venous thrombosis is stated to be favorable for X ray treatment. Three cases treated successfully according to the technique of Basile are reported and a brief summary of the literature on the subject is given.

CRYSTALLINE LENS

Davis, F. A. Capsule forceps for intracapsular cataract extraction. *Amer. Acad. Ophth., and Otolaryng.*, 1937, 42nd mtg., p. 489.

The advantages claimed for these forceps are a smooth biting surface and capability of grasping a large area on the anterior capsule with minimum danger of laceration. (Illustration.)

George H. Stine.

Friede, Reinhard. A modification of the suction apparatus for cataract extraction, and its application. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 573.

A detailed description.

Hurtault, J. B., and Sverdllick, J. Surgical treatment following the reopening of cataract incisions. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, May, p. 251.

Following cataract extraction a sudden severe pain in the eye may indicate reopening of the wound, with prolapse of iris and vitreous. The authors advocate immediate excision of the prolapsed tissue and covering of the upper three fourths of the cornea with a sliding conjunctival flap secured by episcleral sutures. They report a case in which such a complication was treated by this method. Edward P. Burch.

Kovarskaja, S. S., and Krol, A. G. Disseminated subcapsular glaucomatous cataract. *Viestnik Ophth.*, 1938, v. 13, pt. 2, p. 262.

Five cases are reported. Seven eyes had lenticular opacities, characterized by sharply delineated grayish-white opaque foci of varying size and irregular contour, situated immediately under the capsule in its entire visible extent. Such opacities were described by Vogt in 1923 under the name of *cataracta disseminata subcapsularis glaucomatosa*. (Illustrations.) Ray K. Daily.

Marfan, A.-B. Dolichostenomely (dolichomely, arachnodactyly). *Arch. d'Ophth. etc.*, 1938, v. 2, Oct., p. 881.

The author described the first case of this syndrome in 1896. Since then 150 cases have been reported in the literature. It is of particular interest to the ophthalmologist because of the frequency of associated ectopia lentis (50 percent of the reported cases) and other ocular disturbances. The fundamental syndrome includes: elongation and thinning of the bones of the limbs, most marked in the distal extremities; the abnormal height; slenderness and hypotony of muscles; and thinness of the subcutaneous fat. The tendinous contractions are probably only apparent because of the rapid growth of the bones. Dislocation of the lens (which is often small) accompanies rarefaction the zonular fibers, and coloboma of lens, iris, choroid, or lid. The defect is generally bilateral. Of other ocular anomalies which may be present, miosis, amblyopia, and myopia are the most frequent. Less so are enophthalmos, exophthalmos, hydrophthalmos, megalophthalmos, megalocornea, heterochromia iridis, atrophy of the anterior iris surface, persistent pupillary membrane, aniridia, disseminated pigmen-

tion of the choroid, blue sclerotics with fragility of the bones, cataract, nystagmus, and strabismus. Other congenital anomalies are frequently present. The disease is hereditary and familial and its cause is probably an anomaly of development of germinal origin, possibly mesodermal. The theory of hypophyseal dystrophy may probably be ruled out, because in the few autopsies performed the hypophysis has been found to be normal. Treatment is of no avail. (Illustrations, bibliography.)

Derrick Vail.

Strakhow, W. Advantages and disadvantages of intracapsular extraction. *Ann. d'Ocul.*, 1938, v. 175, Sept., pp. 667-678.

Based on his experiences in Moscow and upon the literature, the author lists the following advantages of intracapsular extraction: possibility of earlier operation on immature lenses, relative absence of postoperative iritis (which occurs twice as frequently after extracapsular operation), absence of secondary cataract, better visual acuity. Disadvantages are the necessity for greater manual dexterity and for more perfect instruments. Cases of high myopia and of increased tension are more dangerous by the intracapsular method. Iridectomy is preferred as safer than extraction through a round pupil. Tumbling is not recommended.

John M. McLean.

Van Lint. Extraction of secondary cataract after double incision of the cornea. *Arch. d'Ophth. etc.*, 1938, v. 2, Aug., p. 711.

A new method of extraction of the secondary cataractous membrane is described. Three steps are necessary. (1) Puncture and counter puncture of the limbus are made with the Graefe

knife. The nasal wound is made 5 to 6 mm. long, the temporal one 2 to 3 mm. (2) A cystitome enters the anterior chamber through the small temporal incision, crosses the chamber and is passed behind the nasal iris. Here the blade is turned backward and drawn lightly through the capsule, dragging it toward the center of the pupil. (3) Multiple-toothed capsule forceps are introduced through the large nasal incision and grasp the edge of the capsule, which is then extracted in its entirety by gentle rotary traction. (Illustrations.)

Derrick Vail.

Vogt, Alfred. The cataract discussion at Heidelberg. *Klin. M. f. Augenh.*, 1938, v. 100, Oct., p. 530.

To H. K. Müller's hope of finding a useful remedy for curing senile cataract, Vogt objects that in each of his chemical discussions Müller has confined himself to assumptions, hopes, and debatable hypotheses. From his own observations of single-ovum twins Vogt urges that like other senile signs senile cataract is hereditary, and therefore cannot be influenced by medication. (See also *Amer. Jour. Ophth.*, 1938, v. 21, p. 1172.)

C. Zimmermann.

Vos, T. A. Myotonic-dystrophy cataract. *Ann. d'Ocul.*, 1938, v. 175, Sept., pp. 641-666.

In 39 cases of myotonic-dystrophy cataract, the lens changes were always bilateral but not always equally developed. Some cataracts were of the "Vogt" type, some of the "Fleischer" type, some punctate, and some obscured by senile changes. Genealogic tables of seven families are given and are discussed in some detail. The defect is of the dominant Mendelian hereditary type.

John M. McLean.

Wagner, H., Richner, H., and Karcher, P. Preliminary results of therapy of senile cataract with vitamin B2 (lactoflavin ingestion, controlled by slitlamp microscopy). *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 543.

The experiments showed that an improvement or arrest of the senile cataractous process was not caused by vitamin B2. C. Zimmermann.

Zitovskii, M. L. Comments on intracapsular cataract extraction. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 52.

The author's material consisted of 254 intracapsular extractions. Of these nineteen were with round pupils and the rest had iridectomies. There was vitreous loss in 16 percent of the cases, rupture of the capsule in 6.4 percent, iris prolapse in 2.8 percent, iridocyclitis in 9 cases, expulsive hemorrhage in 2, postoperative glaucoma in 4, choroidal detachment in 3, and purulent infection in 4. Ray K. Daily.

RETINA AND VITREOUS

Boström, C. G., and William-Olsson, L. Thrombosis of central vein of retina successfully treated with heparin. *Lancet*, 1938, v. 235, July, p. 79.

A case of thrombosis of the central vein of the retina is reported in which heparin was given intravenously, with clearing of the lesion and improvement of vision. The authors believe that the heparinized blood coagulates less easily and aids in canalization of the thrombus. T. E. Sanders.

Hildreth, H. R. Surgical ophthalmoscope. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 497. (See *Amer. Jour. Ophth.*, 1937, v. 20, June, p. 626.)

Marmor, J., and Lambert, R. K. Lawrence-Moon-Biedl syndrome. *Arch. Internal Med.*, 1938, v. 61, April, pp. 523-536.

Two classic examples of the Lawrence-Moon-Biedl syndrome, which consists of atypical retinitis pigmentosa, obesity, mental deficiency, genital dystrophy, with polydactylism and of familial occurrence, are reported. The present information points to the fact that pigmentary degeneration of the retina in this condition is a congenital anomaly dependent on an inherited chromosomal factor. This fact suggests that the same may be true of the usual form of retinitis pigmentosa.

T. E. Sanders.

Marshall, J. C. Surgical treatment of detachment of the retina. *Lancet*, 1938, v. 234, May 7, pp. 1033-1037.

In a Hunterian lecture the development of the methods of surgical treatment of retinal detachment is described, including thermocautery, galvanocautery, injection of chemical agents, diathermy surface coagulation, perforating diathermy, electrolysis, and combined diathermy and electrolysis. The last method is described in detail, with indications and contraindications for operating. T. E. Sanders.

Redslob, E. Contribution to the study of the origin of retinal detachment. *Ann. d'Ocul.*, 1938, v. 175, Sept., pp. 637-641.

A globe which was studied histologically shortly after injury showed a very small beginning detachment of the retina. The primary lesion appeared to be a localized dilatation of the veins of the choroid. Immediately over the area was a transudate which had crossed the pigment epithelium and elevated the retina. The transudate had also invaded

the retina, forming cystoid cavities which seemed on the verge of rupturing to form a hole.

Probably several mechanisms are involved in detachment of the retina. Retraction of the vitreous produces negative pressure which allows choroidal vasodilatation to produce a subretinal transudate, with cyst formation in the retinal layers as the precursor of a hole. Either a hole is formed through which vitreous seeps behind the retina, or, in the absence of a hole, choroidal transudate separates the retina.

John M. McLean.

Satanowsky, Paulina. Recurrent vitreous hemorrhages and menstruation. *Arch. de Oft de Buenos Aires*, 1938, v. 13, April, p. 173.

The author discusses the etiology of recurrent vitreous hemorrhage and cites three cases of her own in which the hemorrhages were related to the menstrual cycle. In the first case there was a direct relation between menstruation and the vitreous hemorrhages, which cleared under calcium therapy. None of the usual causes of vitreous hemorrhage were found after careful examination. In the second case the patient had both a positive Wassermann reaction and a positive Mantoux test. The third patient suffered from dysmenorrhea and hypertension.

The author concludes "that the changes produced in the circulatory system of women before and during menstruation are sufficient in themselves to produce vitreous hemorrhages, and that their influence is always manifest even in those cases in which the primary cause of the local vascular lesion is different."

Edward P. Burch.

Veil, P., and Guillaumat, L. Retinal cysts. *Arch. d'Opht. etc.*, 1938, v. 2, Nov., p. 977.

Retinal cysts develop within the layers of this membrane and form lacunar cavities filled with a fluid rich in albumin, but poor in cells. Thus they are differentiated from parasitic cysts, and are closely allied to retinal detachment. They are particularly prone to develop tears, but sometimes, according to Weve, are associated with retinal disinsertion. They are most frequently found in the inferior temporal zone, which location A. Fuchs has attributed to a congenital cause.

From a study of two personal cases and a review of the literature the authors conclude that retinal cysts may be absorbed or may rupture. The absorption may be spontaneous or may be hastened by subconjunctival injection of a 1-to-1000 solution of cyanide of mercury. The cyst may rupture internally (in the vitreous) or externally (toward the choroid). If it breaks into the vitreous its contents are absorbed and scar tissue results, with formation of new retinal blood vessels and a pigmented crescentic cicatricial line. Several clinical forms have been studied. These are multiple cysts, bilateral cysts, and a single cyst with detachment and disinsertion of the retina. The pathogenesis is obscure, but some cases have been associated with long standing iridocyclitis. Weve advises transcleral diathermic micropunctures of the cyst with evacuation of its contents, avoiding the complication of retinal detachment. Others believe that this is too radical. A review of the histologic features of the various forms is made, but more details are needed to complete our knowledge. (Illustrations, references.)

Derrick Vail.

Wilczek, Marian, Hippel-Lindau disease. *Klinika Oczna*, 1938, v. 16, pt. 4, p. 440.

A report of a case in a man 29 years of age, who came with a history of having lost vision of the right eye 1½ years earlier. This was followed by dizziness. Ocular examination revealed retinal detachment and posterior synechia in the right eye and choked disk in the left eye. A diagnosis of cerebellar tumor was made, but at operation no tumor was found. Four months later the left eye presented a typical picture of angiomatosis retinae. Ray K. Daily.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Aronson, G. L. The effect of plasmocide on the eye. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 266.

A report of two cases of optic atrophy caused by administration of plasmocide, in one case in moderate therapeutic doses. Ray K. Daily.

Askalonova, T. M. The effect of therapeutic and toxic doses of plasmocide on the retina and optic nerve. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 26.

A report of a laboratory study on cats. The histologic sections show perinuclear vacuolation in the pigment epithelium, formation of vacuoles between the rods and cones and the pigment epithelium, degeneration of the reticular layers, and haziness of the ganglion cells. In the optic nerve, in addition to degenerative changes, there are inflammatory phenomena such as lymphoid infiltration and destruction of the myelin substance. Ray K. Daily.

Freusberg, O. Homonymous choking of one half of each disc in partial atro-

phy of the optic nerve after unilateral tract lesion. *Klin. M. f. Augenh.*, 1938, v. 100, Oct., p. 494.

A man of thirty years suffered for ten years from headache, vomiting, and epileptic attacks. Through a craniotomy a malignant small-celled glioma of the right frontoparietal lobe was resected. Left spastic hemiparesis and central left-sided paresis of the facial nerve followed, and later, rotatory nystagmus and left-sided homonymous hemianopsia. At autopsy the right primary visual centers were found to be destroyed. Clinically the process had caused a partial degeneration of the peripheral visual paths as shown by left homonymous tract hemianopsia. Then homonymous choked disc had developed in the undegenerated optic fibers. The right nasal papillary half attained a prominence of 4 D., whereas the temporal atrophic half remained at the retinal plane. In the left fundus a difference of level of both papillary halves had not definitely developed.

C. Zimmermann.

Hartman, E., and Guillaumat, L. The fundus picture in intracranial tumors, statistical study. *Ann. d'Ocul.*, 1938, v. 175, Oct., pp. 717-737.

Statistical analysis of the eye grounds in 1,169 patients with intracranial tumor, all verified at operation or autopsy. Gliomas within the brain produce papilledema in 76 percent; meningiomas compressing the brain, only in 40 percent. Tumors of the posterior fossa produce papilledema in 71 percent of the cases. Anterior tumors may produce papilledema without obstructing the aqueduct of Sylvius. Papilledema was found in 50 percent of the cases of encephalitis, but this figure is abnormally high because these pa-

tients were originally seen as brain-tumor suspects. John M. McLean.

Soriano, F. J., and Puiggari, M. I. Retrobulbar neuritis due to beriberi. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, May, p. 244.

A comprehensive review of the history of avitaminosis with respect to vitamin B1 is given, with particular reference to the optic nerve lesion, which is stated to be common among the Japanese. A single case of retrobulbar neuritis occurring bilaterally in a 57-year-old war refugee from Spain is given. There was no evidence of beriberi other than the retrobulbar neuritis. The etiologic diagnosis was based upon the history of malnutrition, the characteristic visual-field changes, and the exclusion of other possible etiologic factors such as tobacco-alcohol intoxication, multiple sclerosis, and diabetes.

VISUAL TRACTS AND CENTERS

Cotlier, I. Psychic concepts of hysterical amblyopia, and fundamentals of psychotherapy and prognosis. *Rev. Oto-Neuro-Oft.*, 1938, v. 13, June, p. 143.

The author gives a comprehensive review of the history of hysteria, with particular emphasis on the viewpoint of modern psychiatrists such as Janet, Charcot, Bernheim, Babinski, and Freud with respect to the ocular type. He feels that although patients afflicted with hysterical amblyopia see images perfectly they transform them by autosuggestion into negative sensory images. "The subject sees with his retina, but not with his cerebrum."

Successful therapy depends upon thorough examination of the patient's

psyche. Whatever type of treatment is undertaken must have for its object establishment of the patient's confidence in his physician. Post-traumatic cases should not receive compensation. In general the prognosis is favorable.

Edward P. Burch.

Mooney, A. J. Lesions of the visual pathway and their relation to neurosurgery. *Irish Jour. Med. Sciences*, 1938, v. 151, July, pp. 315-327.

The visual-field defects of a number of cases with proved intracranial lesions are reviewed, with the following conclusions. Perimetry is of great localizing value in chiasmal and subchiasmal lesions. Perimetry may be the first means of lateralizing a suprachiasmal lesion, but is of localizing value only when considered with the neurological findings. It is essential to follow up the postoperative visual recovery by accurate quantitative perimetry.

EYEBALL AND ORBIT

Anthony, D. H. An enucleation compressor. *Amer. Acad. Ophth. and Otolaryng.*, 1937, 42nd mtg., p. 484. (See *Amer. Jour. Ophth.*, 1938, v. 21, Jan., p. 100.)

Cuesta, Yañez C. Opticociliary neurectomy. *Rev. Oto-neuro-Oft.*, 1938, v. 13, May, p. 117.

The historical background of opticociliary neurectomy is outlined by the author. He describes the technique of the operation and cites five cases in which he has performed it. Three were in painful glaucomatous eyes, another was in a child suffering from panophthalmitis, and the last was in an elderly male with chronic iridocyclitis in an aphakic eye.

Edward P. Burch.

Khaldeev, S. I. Medvedev's method of conjunctivoplasty. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 105.

In four cases of shrunken socket with atrophic eyeball the author enucleated the atrophic eyeball, cut away the cornea and optic nerve, fashioned a flap from the sclera, and sutured it in the wound. In all cases the result was a socket large enough to hold a prosthesis.

Pilman, H. I., and Ilinski, D. T. The temperature induced in the depth of the human orbit by diathermy. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 244.

Two cases were studied, and the charted results show that therapeutic doses of diathermy do not produce any considerable rise in the temperature of the retrobulbar tissues.

Ray K. Daily.

Pimentel, P. C. A case of ocular malformation. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, April, p. 203.

A large, firm, globular mass protruded from the left orbit of an infant. It was removed surgically and was studied microscopically. The optic nerve was not involved and no tumor cells were present. The opinion is ventured that the anomaly was due to invasion of the choroidal cleft by mesodermal tissue elements. (Illustrated.)

EYELIDS AND LACRIMAL APPARATUS

Becker, Fritz. Membranous occlusion of the upper and lower ends of the nasolacrimal duct. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 569.

In two out of an annual average of 250 new-born Becker found on the second and third days of life, without noticeable disturbances of development, a

grayish-red cyst at the medial third of the otherwise normal lower lid. A probe was introduced into the lower canaliculus, and after the probe had penetrated the first occlusion at the entrance of the lacrimal sac a clear viscid fluid oozed out of the lower tear point. Then the probe penetrated the tough resistance at the lower end of the canal.

C. Zimmermann.

Cuesta Yañez, C. Treatment of dacryocystitis by iodine irrigations. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, May, p. 231.

Injection of iodine into the lacrimal sac and ducts for relief of acute and chronic dacryocystitis is reported in five cases. After preliminary anesthesia is established with 2-percent pontocaine solution, a Bowman sound is passed. The tubular sound of de Wecker with its accompanying mandril is passed into the nasal passage. The mandril is then withdrawn and an Anel syringe is employed to irrigate the lacrimal passage with iodine. As the first few drops reach the nose, the sound is withdrawn gradually, pressure on the plunger of the syringe being maintained to insure thorough irrigation of the lacrimal passages. Edward P. Burch.

Grustev, V. F. Functional tests of the lacrimal apparatus. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 402.

The series of tests proposed to determine the function of the lacrimal apparatus are Schirmer's test, the iodine-starch test, response to irritation of eye and nose, and determination of nasal permeability.

Ray K. Daily.

Hollwich, F. Deficiency of lacrimal secretion in small children. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 570.

Physiologically the secretion of tears

is lacking in the infant up to the third or fourth weeks and then sets in gradually. A girl of eighteen months did not shed tears when crying. Under psychical influences the eyes became red but no tears came. Histologic examination of a few lobules of the lacrimal gland showed only hyalin changes of the secretion in some ducts. The skin of the face was dry and peeled off easily in small scales, and the mucous membranes of the nose and throat were dry and showed a tendency to dry catarrh. A congenital disturbance of development of the secretory nerves of the otherwise normal lacrimal gland was assumed.

C. Zimmermann.

Klauber, E. Neurofibromatosis of the eye. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 576.

In 1930 a mentally inferior boy of four years showed an elephantiasis-like thickening of the right upper lid. In 1937 the mentality had improved, but the lid hypertrophy was more striking. Extensive excision produced cosmetic and functional improvement. Histologically the excised piece showed diffuse polynuclear fibromatous proliferation enclosing sebaceous glands, the whole resembling neurofibromatosis. The father had numerous skin proliferations of Recklinghausen type.

C. Zimmermann.

Korkashvili, L. G. Slitting the lacri-

mal punctum. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 405.

For years the author has obtained satisfactory results in epiphora by excising a segment of the posterior wall of the lacrimal canaliculus.

Ray K. Daily.

Offret, G., and Duperrat, R. Ocular manifestations of mullussum contagiosum. *Arch. d'Opht. etc.*, 1938, v. 2, Nov., p. 993.

Mollusum contagiosum localized in the palpebral skin has been recognized for many years. That it can be the cause of severe conjunctivitis or keratoconjunctivitis has not been sufficiently understood. The palpebral type is not easily recognized since it is not always hemispheric, umbilicated, or slow in developing—characteristics of the skin lesions elsewhere. Sometimes it is only slightly elevated, is hidden between the cilia, and may be multilobular. Basing their conclusion on forty cases found in the literature, the authors classify the ocular lesions as (1) conjunctivitis, most frequent and which may be confused with trachoma; (2) keratoconjunctivitis, which may seriously involve vision; and (3) conjunctival tumors, which are very rare and do not produce much irritation. Treatment is by excision or by opening the lesion and sterilizing the interior. A filterable virus is believed to be the cause. (Illustrations, bibliography.)

NEWS ITEMS

EDITED BY DR. H. ROMMEL HILDRETH

640 S. Kingshighway, Saint Louis

News items should reach the Editor by the twelfth of the month.

DEATHS

Dr. Richard Cecil Smith, Superior, Wisconsin, died October 30, 1938, aged 52 years.

Dr. William Humphrys Miller, Terre Haute, Indiana, died October 4, 1938, aged 56 years.

Dr. William Kennedy Butler, Washington, D.C., died October 17, 1938, aged 81 years.

Dr. Willis Bryant Moulton, Portland, Maine, died October 8, 1938, aged 76 years.

Prof. Oscar Oblath, Triest, died June 29, 1938, at the age of 63 years.

MISCELLANEOUS

The sixth Postgraduate Ophthalmological Course was given at the Cleveland Clinic, December 6, 7, and 8, 1938, under the direction of Dr. A. D. Ruedemann, Ophthalmologist in Chief of the Cleveland Clinic. The guest speakers were: Dr. Arnold Knapp of New York City, who spoke on The selection of surgery in glaucoma, and on Ophthalmological developments in the past quarter century; Dr. Avery D. Prangen of the Mayo Clinic, who spoke on Refinements of refraction, and on Types of myopia and management; Dr. Conrad Brens of New York City, who spoke on The results in the treatment of aniseikonia and on The relation of arthritis to eye conditions; and Dr. John Gipner of Rochester, New York, who spoke on Eye muscles and on The treatment of presbyopia. The final speaker of the course was Dr. Wherry of Omaha, Nebraska, who spoke on My son studies medicine. The attendance during the course was 85.

The appointment of Dr. J. Warren Bell as Medical Director of the National Society for the Prevention of Blindness has been announced by Lewis H. Carris, Managing Director of the Society. Dr. Bell was formerly Director of Maternal and Child Health in the State of Nebraska. Before that, he was Director of the Division of Maternal and Child Health in Cattaraugus County in New York State. A native of Minneapolis, Dr. Bell holds degrees of B.S., M.D., and Ph.D. from the University of Minnesota where he was also an instructor and teaching fellow. He served during the World War in the Medical Corps of the 86th Royal Field Artillery Brigade, A.E.F., B.E.F. Dr. Bell is a member of the American Medical Association, a fellow of the American Public Health Association, and a member of the Buffalo, New York, Academy of Medicine. Mr. Carris also announced that Dr. John L. Rice, Commissioner of Health of New

York City, has accepted membership on the Society's Board of Directors.

The National Society for the Prevention of Blindness has announced the appointment of a Nursing Advisory Committee, headed by Miss Katharine Tucker, Professor of Public Health Nursing in the School of Education, University of Pennsylvania. The committee has been selected to represent the various fields in nursing, such as nursing education—graduate and undergraduate—and public-health nursing in its many phases. Each of the federal nursing services is represented by its director. In addition to Miss Tucker, the committee includes: Miss Josephine McLeod, Secretary-Treasurer of the Virginia State Board of Examiners of Nurses, Richmond, Virginia; Miss Ruth Sleeper, Assistant Principal, School of Nursing, Massachusetts General Hospital, Boston, Massachusetts; Miss Cora Shaw, Institute of Ophthalmology, Presbyterian Hospital, New York, New York; Miss Naomi Deutsch, Director of Public Health Nursing, Children's Bureau, Washington, D.C.; Miss Pearl McIver, Senior Public Health Nursing Consultant, United States Public Health Service, Washington, D.C.; Miss Elinor D. Gregg, Director of Nursing, Office of Indian Affairs, Washington, D.C.; Miss Mary B. Hulsizer, Instructor in School Hygiene, Board of Education, Newark, New Jersey; and Miss Marguerite Wales, Consultant in Nursing Education, W. K. Kellogg Foundation, Battle Creek, Michigan. The committee met with Miss Eleanor W. Mumford, Associate for Nursing Activities of the National Society for the Prevention of Blindness, in New York City on December 1, 1938, at which time it was decided that, as a first step, the committee should undertake an analysis of nursing functions which contribute to the conservation of sight.

The Society in addition announces the following report published on one-eyed drivers. One to two percent of drivers are completely blind in one eye, but a more serious problem is presented by the fact that between 20 and 40 percent of all motorists have a deficient eye which handicaps them. No state prohibits either group from driving. This is brought out in a report on "One-eyed drivers," in the current issue of *The Sight-Saving Review*, quarterly journal of the National Society for the Prevention of Blindness. The authors of the report—H. R. DeSilva, W. H. Frisbee, Jr., and P. Robinson—are Research Associates

in the Institute of Human Relations at Yale University.

"Only about 20 states make any check on vision for the driver's license," the report says. "There is, however, no agreement regarding visual standards. A reason for the absence of uniformity lies in the lack of attested facts on the part played by vision in driving. The standards suggested by different individuals or agencies do not conform with one another. The fact that they vary among themselves and are based upon insufficient research shows the need for further investigation."

The authors reached the conclusion that "most one-eyed and deficient-eyed drivers are oblivious to the defects which predispose them to accidents. The greatest human hazard arises not from the defects but from ignorance of the dangers from such defects. For most of these drivers the solution lies in personal reëducation adapted to their individual needs. For others, and especially those who have shown themselves incapable of profiting from reëducation, the solution lies in revocation of their licenses."

The one-eyed person is particularly handicapped in night driving, the report points out, adding: "Not only is a one-eyed person more sensitive to glaring lights, but it takes him much longer to recover from the glare and to see the road clearly again. The one-eyed motorist should drive as little as possible at night."

"The field of vision for a one-eyed individual depends partly upon the protrusion of his good eye and the bridge of his nose. The person with pop-eyes and a small nose will naturally see farther around his nose than a person with deep-set eyes."

"The most obvious compensation for the handicap of having one eye is for the driver to keep his head turned at an angle so as to spread his visual field evenly on both sides. Many one-eyed persons do not compensate nearly enough, since turning the head attracts attention and they are anxious to conceal their defect."

"Another form of correction possible is to keep the head and the eyes roving continually from right to left while driving in order to bring possible dangers from the side into the field of clear vision of the good eye. This habit is unfortunately not common enough among one-eyed persons. The hazards of driving are not the same for the right-eyed and the left-eyed driver, since we steer our cars from the left-hand side and drive on the right side of the road."

The George Washington University School of Medicine, Washington, D.C., announces an intensive postgraduate course in ophthalmology, April 10 to 15, 1939, inclusive. In addition there

is offered a special practical course limited to 25 participants, April 4 to 8, 1939, inclusive. These courses are given by the resident staffs of George Washington University School of Medicine and the Army Medical Museum, and by 17 guest lecturers. For further details apply to the secretary, Miss Louisa G. Wells, 927 17th Street N.W., Washington, D.C. Several members of the American Board of Ophthalmology have consented to interview those taking the course who are prospective candidates for the Board's examination. Information regarding the method and scope of examination will be given.

SOCIETIES

The Eye Section of the Philadelphia County Medical Society held a meeting on January 5, 1939, as follows: Case reports by Dr. Homer Mather and Dr. Ronald C. Moore. Dr. George P. Meyer spoke on Uveal tuberculosis and Dr. Van M. Ellis read a paper on History of sutures used in cataract surgery.

Immediately preceding the Annual Congress of the Ophthalmological Society of the United Kingdom on April 20, 1939, the following meetings will be held at the Royal Society of Medicine, 1 Wimpole Street, London, W. 1: International Association for the Prevention of Blindness (Address 66 Boulevard Saint-Michel, Paris VI). On Wednesday, April 19, the subject will be: The application of the Credé method for the prevention of ophthalmia neonatorum in various countries. The speakers will be Dr. Sinclair (Edinburgh); Professors Terrien (Paris), v. Szily (Munich), Maggiore (Genoa), Vasquez Barriere (Montevideo); Dr. Wilson (Cairo), Dr. Cardell (London), Dr. C. Berens (New York). The International Organization Against Trachoma (address 33 Welbeck Street, London, W. 1), on Wednesday, April 19, at 4:30 p.m. will discuss the subject: The incidence and clinical type of trachoma met with in Europe and North and South America, that is in countries which are commonly considered to be non-trachomatous. The speakers will be Dr. Lavery (Dublin), Dr. Harry Grandle (Chicago), Mr. Arnold Sorsby (London). Subsequently there will be a short discussion on the treatment of trachoma by sulfaphenylamide and its congeners. Members of the Congress are invited to attend these meetings. Ophthalmologists from abroad are invited to attend all meetings of the Congress.

The North of England Ophthalmological Society held its course of annual lectures at the Royal Eye Hospital, Manchester, January 20, 21, 1939, with Professor H. E. Roaf lecturing.

MELANOSARCOMA OF THE IRIS

WILLIAM BROWN DOHERTY, M.D.

New York

The subject of malignancy is not new, but there can be no question that there seems to be an increase in this terrible affliction. In the clinics at the New York Eye and Ear Infirmary melanosarcomata of the uveal tract are by no means rare, but a similar condition affecting the iris is of rather unusual occurrence. It is for this reason that I feel justified in reporting these cases.

Because of the frequency of melanotic sarcoma, the subject of melanosis in ophthalmic literature has of late attracted increased attention, especially in its relation to general metabolism and to the normal functions both of the skin and eyeball. Melanomata, pigmented nevi or moles are either developmental defects or acquired new formations which, for a time benign, undergo slow changes ending in malignant disease. The melanotic pigment, melanin, is now recognized not merely as a side product but is thought to be connected with disturbances of cell metabolism. Localized in special cells, and apparently benign, this pigment seems at times to take some part in the development of malignant extension. Melanotic affections which commence in the eyelids and conjunctiva—extraocular melanomas—present characteristics similar to melanomas of the skin. They are amenable to the same treatment; that is, excision and treatment with radium and the X ray. Intraocular melanotic sarcomata are often beyond the control of surgery once metastasis has actually begun. The removal of

the affected eye often does not prevent the individual from ultimately dying of this affliction. The possibility of distinguishing a disturbance of intraocular pigmentation from an intraocular melanoma changing slowly into a melanotic growth is a consideration from a clinical point of view, and some forms of therapy or surgery present the only hope of preserving the eye and of preventing extraocular extension. There are about 175 cases of iris sarcomata on record and these growths may be pigmented or unpigmented. Of the pigmented group some definitely start in large pigmented nevi which have been noted previously, and there are others which may have started in the stroma of the iris and may have had their origin from small nevi which, being deeply seated, escaped notice. Most of the tumors consist of large spindle cells, and these spindle cells are characteristic of growths derived from nevi.

Melanosarcoma of the iris is most frequent between the ages of 35 and 55 years, and according to statistics is of more frequent occurrence in females than in males. The lower half of the iris is also more frequently affected than the upper. It is difficult to state whether the tumor starts at the root of the iris or in the neighborhood of the ligamentum pectinatum, since these structures usually become rapidly involved with the growth. The beginning of these tumors presents varying clinical appearances which are in all probability due to the site of their origin. In a defi-

nite pigmented nevus the extension is noted by an increase in the size of the tumor, whereas if starting in the deeper layers of the iris near its root the growth

growth to metastasize around the angle of the anterior chamber produces a type of growth known as ring sarcomata of the iris. These cases have been recorded by Werner,¹ Parsons,² Li,³ and others.

Case 1. Melanosarcoma of the iris starting from a benign nevus. G. W., aged 35 years, an Italian with dark complexion, stated that as a child he had always noted a dark pigmented spot on the colored part of his right eye and that he was equally sure that the two pigmented areas on the sclera near the exit of the anterior ciliary vessels were also present as long as he could remember. From his description there could be no doubt but that from early childhood he had had a well-marked melanoma of the iris with two melanotic patches on the sclera below. He experienced no trouble with his eyes until four months previous to his visit to the clinic at the New York Eye and Ear Infirmary, his only discomfort being a gradual loss of vision with no pain. The drawings (fig. 1) well illustrate the ocular condition upon his arrival at the hospital. The whole tumor gives the impression of springing from a melanoma of the iris.

Fig. 1 (Doherty). Case 1, showing lobes of the tumor. Notice small white area in lower part of mass, and pigment spots on sclera.

may spread beneath the stroma and cause varying discolorations which vary from a light yellow to a brown or brownish black. These growths have a tendency to metastasize into the fibers of the ligamentum pectinatum and canal of Schlemm, giving rise to increases in tension. In some cases the tendency for the

It consists of five different areas which are worthy of description. 1. From the patient's statement the temporal side of the mass seemed to be the remains of the old melanoma which was of a cinnamon color. 2. A small round brownish-black colored mass could be seen projecting from behind the iris. 3. There was a large mass of prac-

tically the same color as the mass on the temporal side projecting anteriorly into the anterior chamber. 4. Below, was a larger lobule of the tumor, very much darker in color than any of the other lobes, in the lower part of which there was a small white area. 5. The nasal side of the growth was of the same color as the temporal side and consisted of a number of small lobules. The tension of the eye was 28 mm. Hg.

The patient was informed of his condition and advised to have the eye removed. He desired to consider the matter and returned again to the hospital in 10 days. His eye at this time presented an entirely different picture. He had considerable pain; the cornea was steamy; and a large hemorrhage was present in the anterior chamber. The tension of the eyeball was 56 mm. Hg. The two small melanotic spots in the sclera below disclosed a rather unusual picture. The anterior ciliary vessels were markedly engorged and the two isolated spots were distinctly raised and had the appearance of two small round black beads or two vessels that had been pumped full of black ink. Enucleation was again advised, to which the patient readily consented. The eyeball was removed under local anesthesia and a histological report of a section of the eye was made as follows:

The tumor occupied the region of the ciliary body. It had caused an iridodialysis in addition to replacing the iris on one side. Posteriorly it extended into the choroid for a distance of one centimeter. The cells were uniformly packed with brown or black pigment granules which were so abundant as to obscure their outlines. There were a number of blood vessels and large blood spaces scattered through the tumor. An examination of the depigmented slide revealed an outline of the cells. They were large, oval and round, and disposed in a diffuse man-

ner. The pigment had been largely removed from the central area of the mass, but only partially from the extensions of the choroid and iris. In these locations the pigment occurred densest in the untreated preparations.

I am sorry that an examination of the urine for melanin was not made.

Case 2. I am reporting this case

Fig. 2 (Doherty). Case 2. Above, showing appearance of tumor before operation. Below, showing appearance of iris after operation. Notice small area of growth on lower pillar.

through the kindness of Dr. LeGrand H. Hardy of New York City whom I assisted at the operation in 1930. Mr. W. V., aged 60 years, complained of ocular fatigue upon reading and close work. His general medical history was negative, and there was no history of malignancy in any of his immediate family. He said that he knew he had a spot on the right iris but had absolutely no idea of its duration. Ex-

amination of the right eye was negative in all respects with the exception that the pupil appeared slightly eccentric, pear-shaped, with the apex down and out. A 3-by-3-mm., partially pigmented mass was present at the pupillary border; by oblique illumination it was seen to be spherical and there were several small pigmented spots on the anterior capsule of the lens. The pupil reacted normally to light; the root of the iris seemed clear; the mass apparently was limited within the minor circle. The pupil dilated with atropine, and by transillumination the mass appeared to be partially cystic. The patient was informed of the seriousness of the condition and readily agreed to operative procedure.

Because of the location of the mass on the pupillary border of the iris it was first determined to remove it *in toto* and have it examined; then if it proved to be merely a cyst no further operative procedure would be necessary. The eye was operated on under local anesthesia at the New York Eye and Ear Infirmary, a wide keratome incision being made and extended below with the scissors. The tumor upon being grasped with iris forceps collapsed. The tissue retained within the forceps was withdrawn, pulled upward, and the lower pillar was cut; then downward, and the upper pillar cut; finally, stretching from the base, the root of the iris was severed. At the end of this procedure a pigment spot was seen remaining on the lower pillar. As the anterior chamber was collapsed and the mass appeared to be a cyst it was decided it would be wiser to wait for the pathologist's report rather than risk injuring the lens capsule. An iridectomy on the lower pillar was to be considered later.

The microscopical report on the tissue section was as follows: The specimen submitted consisted of interlacing bundles of oval and spindle cells. Certain

areas revealed a considerable degree of pigmentation, the dark black granules being mostly intracellular. A number of small oval and round cavities were seen throughout the growth. They appeared to be cystic degenerations with walls of tumor cells. The mass was situated mostly on the anterior surface of the sphincter muscle. Vertices of the anterior limiting layer of the iris were visible. Posteriorly, the tumor cells had penetrated between the plate of connective tissue behind the sphincter, reducing it to cloudlike masses of hyalinized tissue. Moreover, the growth appeared to have proliferated around the pupillary area where it must have interposed itself between the iris and lens capsule. The two layers of pigmented cells were readily identified. At one point they seemed to have been separated from each other.

After studying the sections the pathologist advised enucleation. The tumor could apparently be removed *in toto*, but the lack of security and subsequent apprehension made enucleation advisable. The patient agreed that he would rather lose the eye in spite of its perfect vision than be anxiously on the watch for further occurrences. This procedure was carried out, and the lower pillar of the iris examined microscopically presented marked evidences of the original tumor.

Case 3. Seen in consultation with Dr. E. C. Hartman of Parkersburg, West Virginia. In March of 1930 I received a photograph from Dr. Hartman with the following history: Mrs. B. F. B., aged 42 years, had a negative family history. Her past history was irrelevant with the following exception. In 1925 for several months she had had severe headaches on the right side of the head. Dr. Joseph E. J. King of New York City performed a decompression operation and an exploration of the cortex of the brain, but found no pathology. The headache, however,

ceased after this operation. The patient had been married 20 years but had no children.

About 1926 the patient noticed a colored spot on the ciliary margin of the right eye which remained the same size for four years and then began to grow rapidly. The vision remained normal. The general physical examination was negative, the patient being a well-nourished white, adult female weighing 200 pounds; and her height was 67 inches.

From the appearance of the tumor this case seemed to be one of melanosaarcoma of the iris and we both advised enucleation at once. This advice was proposed to the patient, who refused any operative procedure. The tumor continued to grow, and in October, 1931, her eye presented the following appearance: The original growth had increased in size until it was within a few millimeters of the pupillary border; there were also a number of islandlike extensions into the periphery of the iris, and with the slitlamp an almost perfect outline of the large and small vascular circles and some of the connecting branches could be made out. This picture presented itself as minute dots of brown powderlike pigment which were arranged as previously stated. These were situated either in the veins or in the lymphatics, but no definite vessel wall could be observed. The mass did not transilluminate, the tension was 28 mm. Hg, and the general clinical appearance now was that of a ring melanosaarcoma of the iris. Dr. Hartman again advised enucleation, to which she consented.

The following is a report of the pathological examination made by Dr. Bernard Samuels at the Eno Laboratory of the New York Eye and Ear Infirmary: There was some shrinkage of the globe due to the fixation. The anterior stretches of the choroid, the entire ciliary body, and about one half of the iris were replaced on one

side by a highly pigmented new growth. Externally the growth lay firmly on the sclera. It had infiltrated the ligamentum pectinatum and filled with Schlemm's canal. Toward the median line tumor cells were traced anteriorly to Descemet's membrane, to a point beyond the ring of

Fig. 3 (Doherty). Case 3. Above, showing size and position of tumor. Below, stereoscopic photographs taken about 1½ years later, showing the rapid enlargement of the growth, with metastasis around the iris somewhat resembling huge melanomata.

Schwalbe. Extensions of the tumor occurred in the pupillary regions on the opposite side and in the root of the iris and the ligamentum pectinatum.

The growth was composed of small oval cells arranged in interlacing bundles. Pigment epithelium, lining the inner surface for a considerable distance, stood out in contrast. The growth entirely filled out the anterior chamber on this side. The pupillary zone of the iris was directed backward. The tumor touched the lens, causing some pressure atrophy. The retina showed two systems of cystic degeneration, one anteriorly cystic degeneration

Fig. 4 (Doherty). Case 3. Microscopic section of enucleated eye, showing melanosarcoma involving the iris, ciliary body, and choroid, with metastatic tumor on iris of opposite side.

of Iwanoff, which on the side of the tumor extended well beyond the equator. In the posterior segment the second system of cystic degeneration took place in the macular region. The sections did not include the optic nerve, as the nerve was in the macroscopical section. Diagnosis.

Melanosarcoma of the choroid, ciliary body, and iris, with cystic degeneration of the retina.

CONCLUSIONS

1. From the histories of these tumors it is reasonable to suppose that they are

less malignant than those of the choroid or ciliary body. This may be due to the fact that they are more easily observed, and immediately operated upon.

2. A beginning malignancy of a melanoma of the iris, as viewed from a clinical standpoint, would manifest itself by (1) an increase in size; (2) varying discolorations in the same growth; (3) an increased blood supply; (4) elliptical pupil and development of tension.

3. A cyst and a melanosarcoma may co-exist.

4. The so-called ring sarcomas are extensions around the iris from the primary growth.

The question whether pigmentation plays a role in the malignancy of these growths is a much disputed one. I believe it does. A deeply pigmented growth with pigment running wild must mean something. It is true that we do have malignant leucosarcomas, but do they metastasize very rapidly, and do they not occur most frequently in the young?

150 West Fifty-fifth Street.

MECHOLYL AND PROSTIGMINE IN THE TREATMENT OF GLAUCOMA*

SAMUEL T. CLARKE, M.D.

Boston

It is the purpose of this paper to present two new drugs for use in the treatment of glaucoma, particularly of the subacute and acute types, and to discuss briefly the rationale behind present-day therapy in that disease. The new drugs which, so far as I can discover from the literature, have never been used very extensively, if at all, in glaucoma, are Mecholyl (methyl-beta-acetylcholine-chloride), sold by Merck and Company, and Prostigmine ($(\text{CH}_3)_2 \text{N} \cdot \text{CO} \cdot \text{OC}_6\text{H}_5 \cdot \text{N}(\text{CH}_3)_3 \text{SO}_4\text{CH}_3$) sold by Hoffmann-LaRoche Company.

First let us consider the drugs most commonly employed at the present time for the treatment of glaucoma: pilocarpine, eserine, and the epinephrine compounds. The way in which they reduce tension has never been completely and satisfactorily explained, but probably is about as follows:

MIOTICS

Most authors on glaucoma believe that the miosis frees the angle of the anterior chamber and thus facilitates passage of aqueous through Schlemm's canal. In addition, there may be involved specific action on blood vessels and on the formation of aqueous, since these miotics have sometimes been found to reduce tension in the glaucoma of aniridia, in secondary glaucoma with blocked pupil, and in long-standing chronic glaucoma with completely closed iris angle. Their action in these cases is not always dependable.

Pilocarpine. Pharmacologically the primary action of pilocarpine depends upon direct chemical stimulation of the cells in effector organs innervated by the parasympathetic nervous system. A prevalent theory claims the action of pilocarpine to be that of stimulation of the end organs of the parasympathetic. This view is quite fallacious, as can be shown by cutting the nerve supply to an effector organ of the parasympathetic and allow-

*From the Massachusetts Eye and Ear Infirmary. Read before the New England Ophthalmological Society, November 15, 1938.

ing ample time (about two weeks or more) for complete degeneration of all nerve endings and nerves to take place. If pilocarpine is then administered, a greater reaction will be seen to occur than that previous to nerve section, which goes far to disprove that hypothesis. From the best available evidence the action of pilocarpine is directly upon the end organs themselves.¹ Included with this is a slight vaso-dilatory action. It is most effective when used on a glaucomatous eye having a relatively dilated pupil, and when good miosis is obtained following its use. Pilocarpine is the most effective and generally used drug for chronic simple glaucoma.

Eserine is a more powerful and more lasting miotic than is pilocarpine, exerting a strong action for two or three hours. Physiologically the mechanism of its action is different from that of pilocarpine. It seems to depend on its "acetylcholinesterase" inhibiting action, together with certain specific action on parasympathetic effector cells.² The urethane groups in eserine combine with esterase and make it ineffective. This allows the acetylcholine to accumulate by preventing its normal destruction: thus the concentration is increased; hence the cholinergic action is increased. The action of eserine on blood vessels, similar to that in the case of pilocarpine, is one of moderate dilatation. It is a marked synergist to mechoyl, doryl, and other cholinergic drugs. Its disadvantages are that it causes symptoms of hypersensitivity, deteriorates relatively rapidly, and is frequently very unpleasant to the patient, due to the rapidity and strength of its action. Relatively few patients are found who can tolerate long-continued eserine therapy.

EPINEPHRINE COMPOUNDS

Ordinary adrenalin first used by Hamburger (1923) in subconjunctival doses

was supposed to cause a fall in tension, in spite of the mydriasis produced, due to vaso-constriction of the vascular uveal coat; the loss of blood producing a reduction in the volume of the intraocular contents. However, since the maximal effect was noted 12 to 24 hours after the treatment and long after the vaso-constriction had disappeared, Hamburger later concluded that the vaso-dilatation which succeeded was responsible for the effect; the active hyperemia flushing out the capillary bed and perhaps carrying away a certain amount of accumulated intraocular fluid. This explanation is perhaps as good as any other.³

The injections originally given were 4 min. of 1/1000 adrenalin, injections usually being made under the conjunctiva at the temporal side of the globe so as to be near the ciliary ganglion. Such treatments cause a rise in blood pressure generally and in some patients are accompanied by unpleasant systemic symptoms. Hamburger substituted for the ordinary levo-rotatory adrenalin, the synthetic dextro-rotatory adrenalin, which had the same effect on tension but none on blood pressure. This was also used by subconjunctival injection and given the very suggestive name, "Glaukosan."

Since then many different adrenalin compounds have been advocated by various workers and found to be effective by instillation. Among these may be mentioned 1- to 2-percent adrenalin borate or tartrate.

Because it was found that attacks of acute glaucoma not infrequently followed the use of adrenalin, even when used in combination with miotics, certain definite contraindications to its use became recognized. Gifford says that it should never be used in acute or hemorrhagic types of glaucoma and is very sceptical of its value in glaucoma secondary to uveitis.

The ill effects found in these cases are most likely due to the mydriasis which may block the iris angle and hinder filtration. As regards glaucoma, adrenalin compounds have found their greatest usefulness in chronic simple glaucoma, especially when associated with aphakia.

The unpredictability of the action of adrenalin compounds is physiologically explained by the fact that small doses of adrenalin frequently dilate the smaller blood vessels while larger doses do the reverse, and extremely large doses produce great hyperemia by paralyzing all the blood vessels. This varied action combined with the possible effect of mydriasis upon the iris angle makes adrenalin a very uncertain remedy. It is also a very expensive, rapidly deteriorating drug, and occasionally causes a great deal of pain, especially when used in secondary glaucoma.

Theoretically, any drug which either paralyzes the action of the sympathetic nervous system or mimics that of the parasympathetic might be of use in glaucoma. On looking for a possible parasympathetic-mimetic drug, acetylcholine seemed to me to be the logical choice to try as a new drug in the treatment of glaucoma. One other new drug, namely prostigmine, also seemed worthy of trial, as its action closely follows that of eserine.

ACETYLCHOLINE

Acetylcholine or a similar substance is assumed to be produced at all parasympathetic nerve endings and is considered to be the substance responsible for the action of the effector organ.⁴ It is even produced in the sympathetic synapses, although not at the sympathetic nerve endings at the effector organ, where sympathin is formed. The action of acetylcholine is only momentary. This is due to its rapid inactivation by hydrolytic

splitting into choline and acetic acid by the action of an enzyme "acetyl-choline-esterase," which is found in the blood stream and in the tissue juices but not in the normal aqueous. The esterase rapidly appears in the aqueous after disturbances such as paracentesis. This has been proved by experiments on cats.⁵

A cat's blood pressure is lowered quite readily by acetylcholine, but this effect is prevented if aqueous is added to the acetylcholine solution, because the esterase, brought to the aqueous by the trauma of paracentesis, destroys the acetylcholine. This hydrolysis of the acetylcholine can be abolished by the addition to the aqueous of eserine, which prevents the esterase from destroying the acetylcholine. The esterase obtained by the trauma of the paracentesis probably comes into the aqueous primarily from the vitreous, which has a high esterase content, and to some extent from the iris and ciliary body.

Physiologically, acetylcholine is a rapidly acting, strong miotic, although its effect is of very short duration. Cholinergic drugs are all extremely potent vaso-dilators. This latter action occurs on vessels of all caliber and accounts for the good results reported from its use in Raynaud's disease, Buerger's disease, chronic arthritis, and other peripheral vascular diseases.

Uses of mecholyl: 1. Peripheral-vascular disease. 2. X-ray gastrointestinal series. 3. Paroxysmal tachycardia. 4. Postoperative urinary difficulties. 5. Postoperative gastrointestinal distention. 6. Spasm or embolus of the central retinal artery.⁶ 7. Arthritis.

When used in arthritis by the method of iontophoresis, there is, at the site of application, where peripheral vascular spasm has been present, an increase in skin temperature of 4 to 10 degrees Fahrenheit which persists for several

hours. This vaso-dilatory action can be observed directly under the microscope in animals and seems to be greatly enhanced by massage at the site of injection.

Clinically, it is not practical to use acetylcholine because its action is too evanescent. A synthetic drug, mecholyl (Merck), intimately related both chemically and physiologically to acetylcholine, was therefore chosen, instead. The chemical similarity is here shown:

Choline

Acetylcholine

Acetyl-beta-methylcholine
chloride
(Mecholyl)

Mecholyl occurs as a fine, white, crystalline substance that is freely soluble in water. It forms a bitter solution that is relatively stable to heat. The crystals are very hygroscopic and must be protected from atmospheric moisture, but once put up in solution will be effective for as long as a month. Mecholyl has been administered in general medicine by iontophoresis, by mouth, and by injection intramuscularly, but cannot be used intravenously.⁷ It is similar to acetylcholine in action, but is much more powerful, and its action persists for a much longer period. Furthermore, it is devoid of the so-called "nicotine" effect of acetylcholine.

In common with acetylcholine it contracts the pupil, increases the heart rate, lowers blood pressure, constricts the bronchioles, stimulates the activity of the sweat glands and of the secretory glands of the gastro-intestinal tract, increases intestinal tone, stimulates peristalsis, con-

tracts the detrusor muscles of the bladder and anal sphincters, and dilates all the blood vessels of the peripheral vascular system.^{8, 9, 10}

It is a direct physiological antagonist to adrenalin and atropine. After injection, its general effect comes on within 2 minutes and passes off after 20. Large subcutaneous doses make subjects very uncomfortable. Asthmatic attacks and even death can be produced in patients

subject to asthma or other pronounced allergy. Nausea and vomiting are common when large doses are administered and there is a very pronounced fall in blood pressure.

The systemic effects of mecholyl may be instantly abolished by means of 1/100 grains of atropine sulphate given intravenously; and over a period of 5 to 10 minutes, if the atropine is given subcutaneously.

Clinical action of mecholyl, in one respect, is apparently somewhat similar to that of adrenalin, if one accepts Gifford's theory of the action of adrenalin; namely, that it causes an active hyperemia of the ocular vascular bed which carries away accumulated and relatively stagnant blood in the smaller blood vessels. In addition, mecholyl is without the dangerous mydriatic action of adrenalin and it has the decided advantage of being a strong miotic.

Although there is no definite proof

available at the present time, it is my opinion that eventually the action of many of our antiglaucomatous drugs will be found to lie in their effect upon the formation or absorption of aqueous.

My use of the drug at the Massachusetts Eye and Ear Infirmary was started with retrobulbar and subconjunctival injections in acute and subacute cases of simple and congestive glaucoma, and the results were so striking that a 20-percent solution as drops was tried. Retrobulbar injection was found preferable to subconjunctival injection because in a congested eye it is less painful and avoids subconjunctival hemorrhage. Recently, its action as a synergist to another new drug—prostigmine—has been found to be most effective.

By retrobulbar and subconjunctival injection mecholyl is opposite in action to adrenalin; in that it lowers the blood pressure instead of raising it, causes miosis instead of mydriasis, and symptoms of parasympathetic stimulation instead of sympathetic stimulation. It causes a passing redness of the eye instead of a blanching. It is also dissimilar to adrenalin in that it causes great active hyperemia of the ocular blood vessels *immediately*, while the same effect, if it occurs at all, is delayed when adrenalin is used until the primary vasoconstriction has had time to pass off. For this reason and because mecholyl causes an almost immediate sharp fall in blood pressure, it produces a much more rapid and a much greater fall in the intraocular tension than does adrenalin and is strongly indicated in acute glaucoma, while adrenalin is usually definitely contraindicated here due to its causing mydriasis and elevation of general blood pressure.

Unfortunately, this condition of vascular dilatation cannot be expected to persist for long (over one-half hour) with injected mecholyl. Similar action can be

obtained by instilling the drug into the conjunctival sac, but in that case the action will naturally be much shorter in duration, and generally less effective than if the injection method were employed. However, once the pressure is lowered, the amount of drug action needed to maintain the lower level of pressure is much less than that required to bring about the initial drop. At this time, more dilute solutions of mecholyl or preferably of longer-acting miotics such as pilocarpine, prostigmine, or eserine are used to advantage and will usually hold the tension to normal thereafter if miotics alone are to be successful.

Once the pressure has been brought down, surgery can also be used to advantage. The actual surgical procedures will be greatly facilitated technically and there will be less danger of hemorrhage into the eye from the sudden lowering of pressure. This is perhaps one of the greatest values of mecholyl. It will bring down the tension in acute glaucoma so that surgery is more easily and more safely done, and when the general blood pressure and intraocular vascular blood pressure do rise, one-half to one hour later, the blood vessels are relatively constricted as the pressure rises. I have never seen any ill effects coming on at this time from hemorrhage.

Although mecholyl alone has a rather evanescent action, it may be used to advantage over long periods of time as a synergist of eserine, pilocarpine, or prostigmine.

No general symptoms of any kind have been noted following the instillation of mecholyl into the conjunctival sac. Locally, there is a dilatation of the conjunctival vessels lasting about 15 minutes. Following retrobulbar or intramuscular use, however, the following general symptoms and signs may appear, almost immediately:

1. Sweating These symptoms may be extremely severe
2. Salivation and dangerous, especially in old or hypertensive individuals, if extreme doses are given, but if 0.03 gm. is taken as a maximum dose for healthy adults, and 0.010 gm. as probably the minimal effective dose in elderly or emaciated patients, no severe reactions should occur.
3. Fall in blood pressure
4. Nausea
5. Skin feels hot
6. Slight dyspnea
7. Urinary urgency

It is of paramount importance that injection never be given unless atropine in a form suitable for injection is handy—preferably doses of 1/100 gr. This is usually simple as in an emergency the same needle and syringe can be used with 1-percent solution of atropine found in the office of every ophthalmologist as a source of antidote. When given intramuscularly, this will quickly abolish all systemic reaction. If atropine is not given the symptoms pass off in about 20 minutes.

In asthmatic or markedly allergic patients mecholyl injections should never be used because of the danger of sudden death from bronchiolar constriction and respiratory failure, which may be precipitated by the injection.

Case Reports

Case 1. H. A. had an immature cataract with acute exacerbation of glaucoma in the right eye, congestive in spite of 2-percent pilocarpine administered three times daily. Tension in the right eye was 100 plus mm. Hg (new Schiötz). Treatment consisted of 20-percent mecholyl drops given every 10 minutes for one hour, at the end of which time the tension had been reduced—to 14 mm. Hg—

and the pupil being in extreme miosis.

Case 2. J. Y. had chronic glaucoma in the left eye; trephining two years previously controlled the tension, with pilocarpine 1 percent in both eyes as a prophylactic. He now came in with a tension of 38 mm. Hg in the right eye, which in spite of pilocarpine and eserine every 10 minutes for six doses went up to 60 mm. in the right eye in a few hours. Mecholyl, 20 percent in drops, was administered every 10 minutes. In an hour the tension was 14 mm.

Case 3. R. G. had an acute first attack of congestive glaucoma in the right eye, with shallow anterior chamber, steamy cornea, and irregular dilated pupil. The tension in this eye was 92 mm. Hg. After seven doses of mecholyl (20 percent), and prostigmine (5 percent) drops the pupil became smaller, but the tension in the right eye was not reduced below 55 mm. A retrobulbar injection of 0.02 gm. was given and in three minutes the tension in this eye was 12 mm. and stayed there under miotics.

Case 4. A private patient of Dr. F. H. Verhoeff had a first attack of acute congestive glaucoma in the right eye, with steamy cornea, irregular pupil, and almost nonexistent anterior chamber, plus four congestion, tension 125 mm. Hg (new Schiötz). The left eye was white and quiet, but tension was 55 mm. The patient was 72 years old, obese, with a blood pressure of 250/130. After one hour of mecholyl (20 percent) and prostigmine (5 percent) administered every 10 minutes, the tension in the right eye was 50 mm., in the left eye 18 mm. Under the same therapy given every half hour the tension was reduced to 14 mm. in each eye within three hours, and the cornea was clear. The patient was put on mecholyl (20 percent) prostigmine (5 percent) every three hours over night. The next morning the tension in each eye

was 12 mm. She was sent home on pilocarpine (2 percent four times a day) and returned in three days with the right eye acutely congested, the tension up to 90 mm.; tension O.S. 20 mm. Hg (new Schiötz). Under similar mecholyl-prostigmine treatment for two hours the tension in each eye was 14 mm. (n.S.) and the eye whitened for surgery the next day.

PROSTIGMINE

This drug has a pharmacological action similar to that of eserine;¹¹ namely, that it inhibits the action of "A-C"-esterase. It differs from eserine in that it does not cause so much unpleasantness locally to the patient, has a stronger miotic action, and will not deteriorate so quickly as eserine. In addition it can be used in twice as strong concentration as eserine and causes less systemic reaction, such as nausea, when employed frequently as drops. The miosis it produces is usually greater than that caused by equivalent concentrations of pilocarpine and eserine, especially if used in conjunction with its most marked synergist—mecholyl.

Case Reports

Case 1. A. A. had chronic simple glaucoma in both eyes. Four days tension study in the Infirmary gave the following record:

Pilocarpine (4 percent, q.i.d.)

A.M.	Right eye 30	Left eye 36
		(complete blindness in this eye)
P.M.	24	28

Upon shifting to prostigmine (5 percent q.i.d.)

A.M.	Right eye 18	Left eye 26
P.M.	16	20

The patient was finally sent home and the tension was well controlled for four

months. She is now on prostigmine (3 percent) and mecholyl (10 percent), one drop of each four times a day.

Case 2. C. S. had had acute congestive glaucoma in each eye for seven days; worse in the right eye, with extreme chemosis of the conjunctiva, absent anterior chamber, steamy cornea, and dilated pupil.

The tension in the right eye was 77 mm. Hg, in the left eye 56 mm. (n.S.) After one hour's administration of mecholyl (20 percent) and prostigmine (5 percent), 1 drop of each given every 10 minutes, the tension was reduced to: right eye, 36 mm.; left eye, 20 mm.; and in a few hours both eyes had a tension of 20 mm. (n.S.)

Theoretically a maximum miosis or tendency toward producing miosis would be obtained by using:

1. Mecholyl to stimulate the sphincter muscle directly.
2. Prostigmine to inhibit esterase from destroying both the mecholyl and the normally produced acetylcholine.
3. Pilocarpine for its specific action on the sphincter muscle. One might even use ergotamine tartrate subcutaneously, in addition, to paralyze the sympathetic and allow the others an absolutely free rein.

Prostigmine, used alone or in conjunction with mecholyl drops, has shown great promise in the treatment of chronic glaucoma, although sufficient time has not elapsed to allow final conclusions to be made on this aspect of its use. It seems, at least, to be much less irritating than equally effective concentrations of eserine.

At the present time about 25 to 40 patients with chronic, simple glaucoma are being held under control with prostigmine and mecholyl drops. The results are very promising in that many of these patients who had not been so fortunate

under pilocarpine and eserine are having their glaucoma controlled with prostigmine combinations. For chronic use, to avoid unpleasant symptoms similar to those caused by eserine, it is occasionally necessary to use 10-percent mecholyl and 3-percent prostigmine, instead of the 20-percent mecholyl and 5-percent prostigmine used in acute cases.

A good routine treatment for a case of acute congestive glaucoma with

3. Continue the drops for another five doses.

When prostigmine is not available, 0.5-percent eserine may be used instead, for its physiological action is similar to that of prostigmine.

Mecholyl has been used most frequently by the retrobulbar method for acute glaucoma only, and very frequently has brought the tension to normal in from 2 to 20 minutes. Mecholyl injections were

TABLE 1
RESULTS OF MEC HOLYL AND PROSTIGMINE THERAPY OF GLAUCOMA

Type of Glaucoma	Total	Mecholyl (drops)			Mecholyl (retrobulbarly)			Mecholyl and Prostigmine (drops)			Mecholyl and Prostigmine and Pilocarpine		
		+	±	-	+	±	-	+	±	-	+	±	-
Acute congestive	32	2	0	1	14	4	2	8	0	1	0	0	0

Total number treated	100	8	3	2	25	8	3	35	6	2	7	0	1

RESULTS OF ALL CASES TREATED IN THIS SERIES

Number of cases	+	±	-
100	75	17	8
Percent	75	17	8

Legend: + = cases brought to normal tension for minimum of two days, and usually either permanently or until put on other treatment. ± = cases brought to tension of 35 mm.Hg (new Schiötz) or under, long enough to permit a relatively safe surgical intervention. - = cases in which tension was not reduced below 40 mm. Hg (new Schiötz).

mecholyl and prostigmine might be outlined as follows:

1. Morphine gr. 0.25 subcutaneously if pain is marked.
2. Mecholyl 20-percent, prostigmine 5-percent, one drop a.a. given every 10 minutes for seven doses. If the tension has not approached normal after one-and-a-half hours, then inject retrobulbarly, preferably with a retrobulbar no.-25 needle and tuberculin syringe: 0.025 gm. of mecholyl in 1 c.c. of 2-percent procaine.

not used in any cases except those of acute glaucoma because, obviously, one cannot continue to inject any drug over a long period of time. Therefore, it was considered best to use some form of drug-instillation therapy in the chronic cases of glaucoma.

From relatively short experience, retrobulbar injection of mecholyl seems to be a most effective medical way of rapidly reducing high tension in acute glaucoma, whether it be primary or secondary in nature. This should find a wide field of

use in pre-operative glaucoma work, even when the tension is secondary to lens material in the anterior chamber following discission of congenital cataract.

Case. E. O'B., a 35-year-old female in good health, had been needled for congenital cartaract three days previously. She had been suffering from acute congestive glaucoma for 12 hours in spite of the intensive use of 2-percent adrenalin borate and atropine. A retrobulbar injection of 0.025 gm. mecholyl in procaine at the time of operation lowered the tension from 60 mm. Hg (new Schiötz) to 28 mm. in five minutes; at which time the keratome lowered it to almost 0 (new Schiötz) as a linear extraction was started. No complications from hemorrhage ensued.

CONCLUSIONS

1. In this short series, it is interesting to note that in six of the eight cases listed as failures there was subsequent trial of intensive anti-glaucomatous ther-

apy using other drugs. In no case was the status of the patient improved and in four cases it became definitely worse.

2. Of the 61 patients in this series under routine treatment with other anti-glaucomatous drugs when first seen, 41 were using pilocarpine, 10 were using pilocarpine and eserine, and 10 were using epinephrine compounds.

3. Twelve of these patients had previously had intensive pilocarpine and eserine treatment without success before being treated with mecholyl or prostigmine, and in 10 of these the tension was brought to normal.

4. Three patients had had intensive adrenalin-borate treatment before being seen, and two of these were brought to normal.

From the results presented, it would appear that mecholyl and prostigmine may prove of considerable value in the treatment of glaucoma, especially in the acute and subacute stages.

THE RETINA IN SEPTIC AND CHRONIC ENDOPHTHALMITIS OF ECTOGENOUS ORIGIN*

HARVEY D. LAMB, M.D.
Saint Louis

E. Fuchs¹ introduced the term septic endophthalmitis to designate the ocular condition characterized by the exudation of pus cells into the vitreous from the ciliary body and retina following the deposit of toxins in the vitreous. The designation purulent or septic uveitis is not fully applicable because the choroid is protected by the retina from the toxins in the vitreous and is only secondarily involved. In a recent paper, the present writer² reported that in each of 32 eyeballs with septic endophthalmitis of ectogenous origin, at least a few macrophages or exudative cells of chronic inflammation were intermingled with the pus cells in the vitreous. Twenty-four of these thirty-two eyeballs had small round-cell infiltration in the ciliary body and choroid; and the macrophages in the vitreous were generally quite numerous even in the first days of the inflammatory process. Corresponding with the density of the macrophages in the anterior part of the vitreous was the stage of formation of a cyclitic membrane. The condition in these 24 eyes was called complicated septic endophthalmitis.

It is the prevailing kind of phagocytic cell in the vitreous derived from the ciliary body and retina that determines the type of intraocular inflammation. If the microphages or pus cells predominate, septic endophthalmitis is present; if macrophages are rife, chronic endophthalmitis would seem the appropriate diagnosis. The essential factor in chronic endophthalmitis is exactly the same as that

in septic endophthalmitis; namely, the presence of toxins in the vitreous chamber. Whether the inflammatory process is acute, mixed, or chronic depends upon its intensity from high to low, as pointed out by J. Lossen.³ The intensity of the inflammation must vary with the virulence and number of the bacteria present versus the resistance of the infected tissue. Bacteria deposited in the vitreous chamber are, of course, opposed with considerable difficulty since the vitreous contains no blood vessels. Anatomic examination of the eyes with septic endophthalmitis has shown that in an overwhelming majority, a considerable degree of chronic endophthalmitis was present together with the acute or septic process. It is actually, then, a mixed acute and chronic process.

In the previous paper, the relative number of pus cells and macrophages in the posterior or retinal portion of the vitreous were included in a table for each of the 24 eyes with complicated septic endophthalmitis. Although these phagocytic cells in the posterior vitreous were entirely derived from the retina, nothing was reported as to conditions in the retina itself.

In the present paper, there will be tabulated the relative number of pus cells and macrophages coming from the anterior and posterior halves of the retina, the degree of round-cell infiltration in the anterior and posterior halves of the retina (always confined to the inner layers of the retina), the amount of perivascularitis, and whether a connective-tissue membrane on the inner surface of the retina is in process of formation. By the term round cells is meant the macrophages, small lymphocytes, and plasma cells.

*From the Department of Ophthalmology, and the Oscar Johnson Institute, Washington University School of Medicine.

SEPTIC ENDOPHTHALMITIS

There is not included in this study cases of simple septic endophthalmitis since the findings in the retina in this condition are quite uniform. The endophthalmitis in these eyes is in an acute or fulminant stage. The irritant deposited in the vitreous in these cases is so virulent as to cause emigration of almost entirely pus cells from the retina. No perivascularitis of round cells can therefore be present. The number of pus cells from the anterior half of the retina is always much less than from the posterior half because of the richer blood supply to the latter. A dense mass of pus cells frequently observed lying internal to the anterior end of the retina in simple septic endophthalmitis has its source in the adjacent ciliary body where the blood supply is obviously excellent. It is not uncommon in this condition to have the retina entirely destroyed by the virulent toxins in the vitreous.

In the present table, there are included eyes with complicated septic endophthalmitis, now 28 in number, out of 36 eyes of simple and complicated septic endophthalmitis. Only cases of ectogenous origin are used, although those with an endogenous source present exactly the same cytologic changes, as pointed out by E. Fuchs. However, in the latter, a definite time for the start of the inflammation cannot be determined. The principal characteristics of complicated septic or mixed endophthalmitis, as far as the vitreous is concerned, are large numbers of pus cells, at least in its anterior portion or where it is surrounded by the ciliary body, together with numerous macrophages in the same place. In other words, a considerable intensity of the inflammatory process leads to the production of many macrophages. Since macrophages can change to fibroblasts (Lamb⁴) and lead to the formation of a cyclitic membrane along the inner surface of the ciliary body, eyes

with complicated septic endophthalmitis are prone to show the development of connective-tissue membranes on the inner free surface of the ciliary body.

In the table, the eyes are arranged according to the length of the interval from the time of the penetration of the globe to the date of enucleation. As reported in the former paper, the macrophages or exudative cells of chronic inflammation appear almost at once (two days here) in the vitreous internal to the retina. This simultaneous appearance of significant numbers of macrophages with the pus cells must be due to the weakening of the toxins from the vitreous as they penetrate more deeply into the inner layers of the retina. Where the toxins are still virulent or strong, they cause the emigration of pus cells from the retinal blood vessels. As the toxins become weakened by the tissue fluids, they tend to stimulate the production of macrophages. The continuous weakening of the toxins in the vitreous from the defensive bodies in the fluid exudate coming into the vitreous from the ciliary body and retina should influence the inflammatory process to become gradually more chronic or to show proportionally more macrophages in the vitreous. From a study of the table of the eyes with septic endophthalmitis, where in the last eye the inflammation is four months old, it is seen that the general tendency is but slightly toward chronicity. This finding would appear to emphasize the very meager defensive qualities of the vitreous, even after several months' duration of the inflammation.

A study of the number of emigrating cells from the retina into the vitreous shows in the case of both the pus cells and macrophages that they are generally more numerous from the posterior half of the retina where the blood supply is greater. That the latter finding is not entirely uniform must be partly due to the

varying depths of penetration of the etiologic agent.

Pus and red blood cells emigrating from the retina in septic endophthalmitis may detach the vitreous (fig. 1) and come to lie between the unbroken internal limit-

Varying fairly closely with the number of macrophages coming from the anterior and posterior halves of the retina are the relative amounts of round or chronic inflammatory cells infiltrating or lying within these parts of the retina.

Fig. 1 (Lamb). Case 2218. Section through part of eye with septic endophthalmitis, showing pus and red blood cells from retina producing a detachment of the vitreous.

Fig. 2 (Lamb). Case 1132. Section through part of eye with septic endophthalmitis, showing foreign-body giant cells formed from macrophages on the inner surface of the retina.

ing membrane of the retina and the intact hyaloid membrane.

Just as in the case of the anterior or cyclitic portion of the vitreous, the pus cells with their greater activity generally move farther into the vitreous while the macrophages as a rule remain near the inner surface of the retina. On account of the latter, the retinal membrane developed from the macrophages in the vitreous lies close to the retina. The effect of the toxin in the vitreous may exceptionally lead to the formation from the macrophages of foreign-body giant cells on the inner surface of the retina (fig. 2).

Since all the inflammatory cells infiltrating and coming from the retina must arise within or around the retinal blood vessels, the perivasculitis is by far the most significant feature of the reaction of the retina to toxins in the vitreous. Perivasculitis, in at least a mild degree, was present in all but 2 of the 28 eyes with complicated septic endophthalmitis. A moderate intensity of perivasculitis was present in 8 eyes and an intensive degree in 2 eyes of this series. In eyes in which the inflammatory process was not more than two weeks old, but in a majority of the longer-inflamed eyes also,

only macrophages form the infiltrating cells of the perivasculitis and of the adjacent inner layers of the retina (figs. 3 and 4). Within the lumina of the affected blood vessels, monocytes are commonly observed together with pus cells. Maxi-

eyes, small lymphocytes and plasma cells together with macrophages infiltrated the inner layers of the retina adjacent to the blood vessels that presented perivasculitis. The small lymphocyte in the retina can only come from the blood. It is gen-

Fig. 3 (Lamb). Case 2119. Section through part of eye with septic endophthalmitis showing retinal perivasculitis composed of macrophages. At the periphery of the bloodstream on the right, there occur numerous monocytes.

Fig. 4 (Lamb). Case 1899. Section through part of eye with septic endophthalmitis showing retinal perivasculitis composed of macrophages and numerous monocytes within the bloodstream. To the right on the inner surface of the retina, macrophages from the retina are elongating into fibroblasts.

mow⁵ derives the macrophages of inflamed tissue much more commonly from the lymphocytes and monocytes of the blood than from the local histiocytes situated around the blood capillaries. Among the present series, in seven eyes, small lymphocytes and plasma cells participated in the perivasculitis. In all seven eyes, the inflammation had been present for two weeks and more. In the case of these seven

erally agreed that the plasma cell is derived from the small lymphocyte.

Keller⁶ reported two cases with retinal perivasculitis in septic endophthalmitis. In the first case, the eye was removed four weeks after a perforating injury through the cornea and adjacent sclera. A moderate degree of septic endophthalmitis had caused an exudation of pus cells from the anterior portion of the

retina. Posteriorly, there was present no exudate of pus cells from the retina but an intensive degree of perivasculitis. In the second case, through the use of intramuscular milk injections, the vitreous became sufficiently clear to obtain the very unusual ophthalmoscopic picture of retinal perivasculitis. Posteriorly, along the veins only, there occurred 16 well-disseminated, small, white, fairly well-circumscribed spots. In the following few days with the healing of the eye, these spots entirely disappeared. This valuable contribution emphasized the overwhelming involvement of the retinal veins over the arteries and the focal arrangement of retinal perivasculitis.

CHRONIC ENDOPTHALMITIS

For comparison with the eyes having septic endophthalmitis, seven eyes with chronic endophthalmitis are included in the table. The difference in the retinal findings of the eyes with chronic endophthalmitis as compared with those having septic endophthalmitis is striking in respect to the intensity of the inflammatory process. The retinal macrophages were generally much less numerous in chronic endophthalmitis than in septic endophthalmitis. The retinal perivasculitis was not so intensive, causing less infiltration of round cells in the retina and fewer macrophages in the vitreous. Small lymphocytes are only occasionally observed among the perivascular macrophages and in the retinal infiltration of chronic endophthalmitis. Nevertheless there were enough inflammatory changes in the retina of these eyes with chronic endophthalmitis to demonstrate that the essential etiologic factor (the presence of toxins in the vitreous) is the same as in septic endophthalmitis. This fact was clearly confirmed beyond any dispute in all seven eyes by the presence of numerous macrophages on the inner surface of

the ciliary body. The much better blood supply in the ciliary body as compared with that in the retina would explain the greater number of macrophages emigrating from the ciliary body through chemotactic action of the toxins in the vitreous. The choroid presented very little cellular infiltration in these eyes with chronic endophthalmitis with the exception of case 2304. Here the choroid was a little thickened by dense infiltration with small lymphocytes and plasma cells occupying its external layers. In the writer's recent article² similar infiltrations of the choroid were reported as occurring in septic endophthalmitis and being due to toxins in the vitreous. In case 2304, the retina was considerably degenerated and therefore more porous to toxins in the vitreous.

It is true that in the tabulation, eyes with chronic endophthalmitis are greatly outnumbered by those with septic endophthalmitis. Nevertheless there are sufficient cases to demonstrate clearly that, as a rule, in chronic endophthalmitis, the macrophages or exudative cells of chronic inflammation are considerably less numerous than in septic endophthalmitis. In the latter, a much greater intensity of the inflammatory process prevails than in chronic endophthalmitis.

As regards the spontaneous formation of connective tissue on the inner surface of the retina or retinitis proliferans, Leber⁷ wrote in considerable detail. After serious injuries to the eye, this formation of connective tissue occurred in the midst of red blood cells, rarely in the presence of inflammatory exudate on the inner surface of the retina. This new formation of connective tissue was known as organization. With other observers, Leber considered the essential process to be combined with a hyperplasia of the supporting structure of the retina. In our series, the formation of connective tissue

on the inner surface of the retina was noted in six eyes with septic endophthalmitis and in none of the seven with chronic endophthalmitis. As illustrated in figure 5, it can be seen that fibroblasts develop from macrophages to form this

hyperplasia of the neuroglia cells or supporting structure of the retina always occurs to some degree in every degenerated retina. Secondary degeneration of the retina invariably accompanies any serious case of endophthalmitis. If the connective

Fig. 5 (Lamb). Case 1899. Section through part of eye with septic endophthalmitis showing macrophages coming from the retina on the left, in the process of developing into fibroblasts.

Fig. 6 (Lamb). Case 1132. Section through part of eye with septic endophthalmitis showing on the right an incipient connective-tissue membrane formed from and infiltrated with retinal macrophages.

connective tissue on the inner surface of the retina just as in the case of the cyclitic membrane (Lamb⁴). In figure 6, a thin layer of connective tissue produced from retinal macrophages is presented. This is all that organization of a hemorrhage or of an inflammatory exudate within the vitreous can ever mean. The

tissue developed on the inner surface of the retina is a neuroglial structure, it will not stain red with the acid-fuchsin of Van Gieson's stain, as it does. This layer of connective tissue is appropriately termed a retinal membrane.

As to the rapidity with which this connective tissue forms it is noted in the table

for case 999 that fibroblasts on the inner surface of the retina were developing from macrophages seven days after the start of the inflammation. In addition, two weeks after the etiologic penetration in case 1330, connective tissue in this situation was beginning to be produced by fibroblasts, derived from macrophages. Of course, contraction of this new-formed connective tissue sooner or later leads to retinal detachment, but since the eyes in these cases were already destroyed by irreparable injury to the ciliary body (Lamb²), the sequelae of cyclitic or retinal membranes were not of much clinical importance.

SUMMARY

The principal retinal changes are tabulated in the case of 28 eyes with septic endophthalmitis and of seven eyes with chronic endophthalmitis. The 28 eyes with so-called complicated septic endophthalmitis were characterized by at least a small amount of small round-cell infiltration in the ciliary body and choroid together with the exudate of numerous pus cells and macrophages into mainly the anterior or the cyclitic portion of the vitreous. The term chronic endophthalmitis is introduced as a corollary to septic endophthalmitis for the clinical and pathologic diagnosis of eyes showing an exudate into the vitreous that is composed

almost altogether of macrophages. The retinal change occurring first in endophthalmitis was perivascularitis. The latter was the source of all the inflammatory round cells that infiltrated the retina and migrated into the vitreous from the retina. In all the eyes tabulated, the macrophage was the predominant cell composing the perivascularitis. Perivascularitis in some degree was present in all but two of the 28 eyes with septic endophthalmitis and in all but two of the seven eyes with chronic endophthalmitis. The number of round cells infiltrating the retina and the number of macrophages from the retina entering the vitreous were generally fewer by far in chronic endophthalmitis than in complicated septic endophthalmitis. The retinal membrane on the inner surface of the retina like the cyclitic membrane was composed of connective tissue produced by fibroblasts that developed from the macrophages in the vitreous. This retinal membrane is more likely to occur in septic endophthalmitis than in chronic endophthalmitis because more macrophages develop in the former.

All the sections of eyeballs and photomicrographs used in this study were prepared in the Laboratory for Ophthalmic Pathology, Washington University School of Medicine.

OCCUPATION IN RELATION TO CANCER OF THE EYE AND ADNEXA*

WITH PRACTICAL POINTS FOR THE OPHTHALMOLOGIST

LAURA A. LANE, M.D., F.A.C.S.

Ann Arbor, Michigan

The medical literature of Great Britain, France, Germany, and, to a lesser extent, that of America contains articles dealing with occupational cancer. No specific articles on cancer of the eye and adnexa have been found. Kenneway,¹ in an article concerning the anatomical distribution of occupational cancer, found 11 cases of eye and eyelid epitheliomas among 100 pitch workers, and 2 cases among 33 tar workers. Among 38 persons who had 75 cancers due to arsenic only one case in which the eyelid was involved was found.

Among 21,510 patients suffering with neoplastic disease, seeking treatment at Memorial Hospital, New York City, during a period of 13 years, Haagensen² found 208 cases of ocular cancer (not all were verified by biopsy).

At the 1936 meeting of the American College of Surgeons the writer presented a report³ on an occupational study of cancer of the eye, setting forth the results in 1,000 patients. The cases were equally divided between carcinomas and malignant melanomas.

SOURCES OF MATERIAL

The material used in this study was obtained from the following sources:

- (1) From the records of 22 eye clinics in different parts of the United States and Canada.
- (2) From the records of four institutions devoted exclusively to the

study and treatment of cancer.

- (3) From the private records of many eminent ophthalmologists.
- (4) From medical services of large industrial plants producing chemicals, oils, carbon products, and gas.

Every case studied has been verified by biopsy or microscopic section of the tumor.

CLASSIFICATION OF OCCUPATIONS

More than 154 different occupations were represented in this collection of ocular tumors. There was some difficulty in condensing and grouping such a large number. The following classification was made:

Group I. Occupational groups exposed to oils and lubricants.

Group II. Occupational groups exposed to sunlight.

- (1) Occupations with considerable exposure to sunlight and the elements.
- (2) Occupations with exposure to sunlight and tar (Group IV, 2).
- (3) Occupations with exposure to sunlight, chemicals, and irritants.

Group III. Occupational groups exposed to chemicals.

Group IV. Occupational groups exposed to (1) coal, (2) pitch and tar.

Group V. Occupational groups exposed to radioactive substances as radium and roentgen ray.

Group VI. A large group of miscellaneous occupations such as: Clerical, domestic and personal, construction, engineering, professional, manufacturing, transportation, and trades—affecting

*From the Department of Ophthalmology of the University of Michigan. Read before the Eye, Ear, Nose, and Throat Section of the Tarrant County Medical Society, Fort Worth, Texas, March 4, 1938.

business men, merchants, salesmen, and others.

Group VII. A comparatively small group of workers in metals.

LACK OF OFFICIAL OCCUPATIONAL CANCER STATISTICS

Official occupational-mortality statistics, tables of age distribution in occupations, and cancer-morbidity rates, except those in a few states and the data of the Metropolitan Life Insurance Company are not available in this country. Britten⁴ in 1934 made an occupational-mortality cancer report. It concerned men only and covered 10 states. The data were derived from the 1930 United States census material.

Hundreds of records in eye clinics and in ophthalmologists' offices failed to record the occupation of patients, and this is a very important item in a cancer history. In general cancer work it is now recognized that an increased cancer incidence exists in those occupations involving chronic irritation and prolonged exposure to aniline, anthracene, arsenic, creosote, paraffin, petrolatum, pitch and tar, radium and roentgen ray, shale oil, and soot.

GROUPING OF THE CASES BY NEOPLASMS

The eye records chosen for this study were grouped under the two principal malignant-tumor classifications; namely, malignant melanomas (sarcomas), or the connective-tissue type, and the carcinomas, or epithelial-cell type.

There were 500 cases equally distributed in each classification. Other malignant tumors involving the eye and adnexa are very rare and are of no great importance in an occupational study. Retinoblastomas occur before the eighth year of age, as a rule, and do not present an occupational problem.

It will at once be seen that there is a

striking similarity in the occupations, also in the number of cases of each type of cancer in Group I. A total of 37 cases per 1,000 is high. It indicates an increased cancer distribution among those whose occupations exposed them to oils and lubricants (table 1). The general cancer rate is 8 for females and 11 for males per 1,000.

Oils produced in the United States except in the Middle West oil region where oils have a higher paraffin and asphalt base, do not have such high carcinogenic properties as do foreign oils. American oils contain less sulphur than do foreign oils. Refining in the United States is largely a closed process; the workmen have little contact with the oil. One of the largest oil companies, employing thousands of workers, with records extending over many years, shows a surprisingly small number of cases of cancer of all parts of the body.

Group II may be called the solar group, and it was found desirable to divide it into three subdivisions, as follows: (1) A larger group, composed of semiskilled and unskilled workers, whose occupations exposed them much to sunlight and the elements. (2) A smaller group whose occupations relate to the sea, exposure to sunlight, and to a known carcinogenic agent; namely, pitch and tar of Group

IV. (3) A third division of only three occupations, skilled in character, where workers are exposed not only to sunlight but also to chemicals and trauma.

Group II has more than 2.8 times (the exact number is 204) the total number of cases found in all the other groups except Group VI, the miscellaneous group.

In Division 1 attention is called to the large number of farmers and laborers having carcinomas, 98 in number. Others in this country and abroad have noted the same thing.^{5, 6}

As to Division 3 of Group II, English writers have called attention to the large number of carpenters having neoplasms. Many attribute this to trauma. Our study of ocular cancer does not bear this out. Only one patient in our series gave a history of trauma. We believe the occupational hazard is due to the handling of creosoted shingles, of composition roofing which contains much tar and asphalt, and of building papers, also other lining products many of which are chemically treated. Carpenters are exposed to fine particles of these products in addition to sunlight. Seven carpenters had a basal-cell tumor of the eyelid. Four had a squamous-type tumor. More than half of these men were in the sixth and seventh decades of life and the remainder were between 47 and 52 years of age. Of the malignant melanomas in carpenters, seven tumors were in the choroid, one in the iris, and two in the conjunctiva.

Painters have a potentially increased distribution of ocular cancer. Chrome is a decided chemical irritant and frequently enters into the composition of paints.

A very small distribution of ocular cancer was found among those whose occupations involved a considerable use of chemicals. Some 40 operations, mostly chemical, are used in the process of tanning and preparing leather. Only one leather tanner was found. This patient

had a melanosarcoma of the choroid which had no possible connection with his occupation.

Arsenic is a chemical which frequently produces malignancies of the skin. This study has not disclosed an ocular neoplasm among arsenic workers or arsenic users.

Our survey material has drawn heavily upon territories adjacent to the three large coal-industry areas of Pennsylvania, West Virginia, and Southern Illinois. The records of eight institutions receiving patients from these coal areas yielded histories of only five coal miners with a cancer of the eye. The literature does not indicate an increase of cancer among coal miners and our data corroborate this.

Concentrated coal products such as pitch and tar derived by distillation of coal are potent carcinogenic agents. Gas-house workers show a rather high cancer incidence in other parts of the body but not in the eye.

A definite occupational hazard in the handling and use of radioactive substances has been known for years. Many of the lesions are of a squamous-cell-carcinoma type.

Four eye cases were collected. Three of these had other cancer lesions than those of the eye. One of the nurses had been treated years before for a lupus which involved the cheeks. Protection had not been given to the eyes. She had a squamous-cell lesion of the lower lid. The other nurse had been a handler of radium for many years and developed a lymphatic leukemia with eye lesions. One of the

physicians had a basal-cell type of carcinoma involving the face, eyelid, and forearm.

On record are now some 150 cases of carcinomatous lesions developing in different parts of the body in workers long exposed to radioactive agents such as roentgen rays⁷ and a smaller occupational group of radium workers who have developed osteogenic sarcomas and lymphatic leukemia. The radioactive occupational hazard to the eye does not appear to be very great.

Nearly three fourths of the 1,000 cases fall in Group VI. The occupations in this group are of a more or less sedentary nature. Most of them are indoor occupations without much exposure to sunlight or to known cancer irritants. Many semi-skilled and unskilled occupations as well

as highly skilled occupations are included in this group.

as "occupation none, retired and aged," there is a large predominance of malignant melanomas. The professions, public service, and transportation groups have nearly the same number of cases in each type of neoplasms.

The unemployed show almost seven times more carcinoma than sarcoma cases. This is accounted for by the much older age incidence of the carcinoma patients.

TABLE 7

Total	9	Total	6

This occupational group is not large. There is an increased distribution of cancer of the eye for the group as a whole. Most of the metal industries use one or more chemicals in connection with the manufacture of their products. In certain divisions of the iron industry sulphuric acid is used for bleaching in making gray iron castings. Workers are exposed to frequent splashes. Some of the patients gave a long history of exposure in their work. The tin worker had been employed by the same firm for 20 years.

As a rule it takes from 10 to 15 years' exposure to an irritant before precancerous or cancerous lesions develop.

REVIEW OF THE GROUPS

Table 8 shows four groups which have an increased distribution of cancer of the eye. However, not all the occupations in these groups show an increased distribu-

Table 6 shows 89 more cases of malignant melanomas (sarcoma) than carcinomas. The clerical occupations have three times as many cases. The domestic and personal-service occupations show 11 more melanomas. The manufacturing and mechanical industries have doubled the number of melanomas lacking one case. In the student and child group there are over four times as many cases as in the carcinoma group. There are nearly twice as many in the trades as in a similar carcinoma group. In the group designated

TABLE 8

tion above that found in the average general cancer rate per 1,000 cases. Occupations in which workers are exposed to oils and having relation to the automotive field show some increased distribution. Printers, plumbers, and steam fitters, who use oils more or less in their work, do not show any such increase. Group II, comprising occupations wherein workers are exposed to sunlight, the elements, pitch and tar, and chemicals, shows a large distribution. Especially to be noted is the large number of farmers and of laborers who form 85 percent of the 155 cases in this group.

In the large miscellaneous group whose workers have more or less sedentary occupations which present no great occupational hazards, there is a rather startling increase, particularly in the domestic and personal-service occupations, more than one third of the entire 1,000 cases being in housewives. Individually the clerical occupations show no increase, but taken as a group they do. Likewise, the manufacturing and mechanical industries as a group show considerable increase. Group VII is a small select group of skilled artisans, mostly the male sex, with no individual increase in cancer of the eye, but the group as a whole shows a slight increase. Another point of interest to the ophthalmologist is the anatomical distribution of the eye lesions, as well as the age and sex distribution.

The anatomical-distribution chart shows that carcinomatous lesions are confined largely to the adnexa and to those parts most exposed to occupational irritants and traumas. A very different picture of the number and of the anatomical distribution of the sarcomatous lesions is seen (table 9).

The average age of the 500 patients having ocular carcinoma was 57.15 years. The average age of those with a similar number of malignant melanomas (sarcoma) was 48.5 years. There were 201 females among the 500 carcinoma cases and 214 among the 500 sarcomas, making a total of 415 in both types of cancer. Of the males we find 299 among the 500 carcinomas and 286 among the 500 malig-

nant melanoma cases, or a total of 585 in the 1,000.

It will be seen that there is an excess of 170 males over females; however, five of the seven occupational groups had occupations in which, as a rule, only men are engaged. Much of our material was drawn from large industrial centers, which may possibly account for the predominance in men.

Data on heredity was too incomplete to be of any value, as was also information on the duration of symptoms before treatment was started.

This study brought out the fact that the number of cases of cancer of the eye over a period of 7 to 30 years in many of the clinics shows no increase. The number of cases in each type runs constant. The only rise was in the number of sarcoma cases immediately following influenza epidemics.

The following points should be given attention by ophthalmologists when taking cancer-of-the-eye histories. It is exceedingly important to know how long a patient has followed his occupation. Likewise, whether any other occupation was followed previous to the present occupa-

tion and if so, how long that occupation was pursued. These questions often have an important medico-legal bearing. Instances are found in the literature and in this survey material in which a patient suffering with a cancer had changed his occupation. This change in occupation had for a time led to a decrease in the growth. Such a patient should be classified under the primary occupation and is not entitled to compensation.

The exact nature of the duties of the occupation should be noted. Is the patient working more or less constantly with known cancer irritants? A plea is made that every person who takes a cancer history of the eye get a complete and full history of the patient. Details are of importance in solving the cancer problem. Good follow-up records are of great importance in cancer work. Eye clinics, unfortunately almost without exception, have not been in the habit of following up their tumor cases. In the institutions for the study and treatment of malignant disease, the records are far better, and good follow-up work has been going on in many of them for more than five years.

CONTRAST SENSITIVITY AS A CRITERION OF VISUAL EFFICIENCY AT LOW BRIGHTNESS-LEVELS*

MATTHEW LUCKIESH, D.Sc. AND FRANK K. MOSS
Cleveland, Ohio

It is generally conceded by ophthalmologists that visual acuity is the most important ocular requirement for the licensure of automobile drivers, and proposed visual standards are usually based upon this criterion.¹ This conclusion involves the assumption that the determination of visual acuity with test objects of maximal contrast under photopic conditions is appropriate and adequate for the purpose of driver-testing. However, under low brightness-levels, such as exist on streets and highways at night, most hazards are large in size and of relatively low contrast. Therefore, it is interesting to study the individual variations in contrast threshold among motor-vehicle drivers and others subjected to similar conditions. This visual function is not necessarily measurable by the usual techniques of determining visual acuity,² as is evident from the data presented in this discussion.

The present investigation of the differences among individuals in the perception of low contrasts under low brightness-levels involved 50 adult subjects of an average age of about 30 years. These subjects possess *binocular*-visual-acuity ratings as follows: 39 subjects with 20/20 vision, 6 subjects with 20/40 vision, and 5 subjects with 20/60 vision. These data were determined with the 1932 American Medical Association chart uniformly illuminated to a brightness-level of about 6 foot-lamberts. This brightness is equal to that of a perfectly white, diffusely reflecting surface under an illumination of 6 foot-candles. Binocular measurements

were made as a matter of convenience in accumulating these data, although it was recognized that the usual monocular measurements are preferable in practice. In general, our subjects were free from visual defects arising from pathological causes. However, 26 of the 50 subjects wore eyeglasses, although some of these wore corrections only for near work.

The data of figure 1 show the relationships between measurements of visual function as determined with (1) the 1932 American Medical Association test chart at a distance of 20 feet, and (2) the Luckiesh-Moss Low-Contrast Test chart at a distance of 10 feet. The latter distance was selected merely from considerations of the visibility of the test objects of the low-contrast test chart. The latter consists of pairs of digits of modified Snellen design reproduced in various degrees of contrast with their dull white backgrounds as shown on the right-hand scale of figure 1. These test objects subtend an average over-all angle of about 35 minutes at the test distance of 10 feet. The critical details of the test objects subtend a visual angle of about 7 minutes at a distance of 10 feet. This is equivalent to a 20/140 Snellen rating. However, the size of each digit was individually fixed so that all of the digits used are of the same visibility for the same degree of contrast. Both charts were placed upon a white field approximately 5 by 6 feet and were *uniformly* illuminated to a brightness of 0.01 foot-lambert. This field may be considered as simulating a road surface. A 10-minute period was allowed for adaptation to this arbitrary brightness-level.

*From the Lighting Research Laboratory, General Electric Company.

Fig. 1 (Luckiesh and Moss). The correlation between measurements of visual function determined with (S) objects of maximal contrast and various sizes, and (C) objects of various contrasts and constant size.

In general, it will be noted from figure 1 that the subjects possessing the same visual-acuity rating, as measured by the American Medical Association chart, varied rather widely in their ability to recognize the low-contrast test objects of the Luckiesh-Moss chart. For example, the threshold values of contrast varied from 20.7 percent to 11.0 percent for the group of subjects who were able to "read" line 6 of the American Medical Association chart. In this respect, it will be noted that the subject with the best vision among those who were barely able to read line 9 on the American Medical Association chart was visually equivalent to the subject with the worst vision among those who could barely read line 6. Thus many objects on the highway which would be visible to some of these subjects would not be seen by the others.² It is also probable that even greater differences in the thresholds of contrast would be obtained among a group of subjects possessing visual defects of a pathological character.

The coefficient of correlation between these two sets of measurements is 0.81. The magnitude of this datum is due to a large extent to the fact that the values corresponding to the lowest degrees of visual efficiency (American Medical Association scale) were obtained for 14 subjects without their usual corrections as well as with them, thus accounting for 64 plotted points on figure 1 obtained from 50 subjects. If the additional 14 sets of data are excluded, the coefficient of correlation is reduced to less than 0.60. This is a statistical indication that the two charts are not equivalent

as means for revealing individual differences in visual ability or visual function. In other words, it does not appear possible to use the American Medical Association chart as a substitute for the contrast chart even under low brightness-levels.

At low levels of brightness where contrast perception is a very important factor in seeing, the influence of both "corrective" and "tinted" lenses deserves some consideration. Even clear glasses reduce the brightness of objects at least 8 percent which is sufficient to depress below the threshold of visibility objects which are normally above the threshold. Obviously tinted glasses, which reduce the brightness still more than clear glasses do, will depress additional objects below the threshold of visibility. This applies to windshields as well as to lenses.

Some interesting observations were made pertaining to the effect of corrective glasses on the 14 subjects whose contrast thresholds were determined with and without them. In one case the contrast threshold was appreciably decreased when the subject removed his glasses. In some cases little difference was noted. In others considerable increase in contrast threshold resulted from the removal of the corrective glasses. These are matters of interest in addition to the general application of the criterion of perception of contrast in the determination of visual efficiency, particularly at low brightness-levels. In fact, throughout the realm of seeing, contrast sensitivity is deserving of more attention than it has received.

TREATMENT OF GONORRHEAL OPHTHALMIA*

A. G. BOWER, M.D. AND WILLIAM FRANK, M.D.
Los Angeles, California

Before the advent of sulfanilamide, the treatment of gonorrheal ophthalmia was long, difficult, and disappointing. An average of 20 days elapsed before the first negative eye smear was obtained, and an average of 27 days was required for the treatment of the active infection. Too often vision was lost or severely impaired.

When reports of the successful treatment of gonorrheal urethritis with sulfanilamide became known, we determined to use the drug in our routine treatment of gonorrheal ophthalmia. Starting in June, 1937, we have had to date a series of 21 patients so treated, in which 18 have responded very satisfactorily with a first negative eye smear in two days, and in which the time of local treatment has averaged 10 days. Of these 18 patients, 10 were adults; two were children, five and nine years of age, respectively; and six were infants under 30 days. In this group, when the cornea was uninvolved on admission, vision was entirely preserved. In no case did corneal perforation occur. All the failures were in infants, two of whom were premature. In this series the number of days of local treatment required for cure is reckoned as the number of days that elapsed before irrigations could be reduced to every three or four hours *pro re nata*.

The treatment may be divided into two parts, local and general; each part is indispensable for best results. The local treatment consists of:

(1) Irrigation of the conjunctival sac every 10 to 15 minutes as long as pus is obtained. As the infection subsides and the formation of pus diminishes, the time

interval between irrigations is lengthened. Boric-acid solution or normal saline solution is used for the irrigation.

(2) One-percent atropine-sulfate solution instilled into the conjunctival sac as often as necessary to keep the pupil fully dilated.

(3) Ten-percent argyrol instilled into the conjunctival sac every hour until negative eye smears are obtained. This is probably unnecessary in most cases. We now have five patients, four adults and one infant, treated without argyrol, who have responded just as readily as those who received argyrol. We feel that the use of the mild silver salts can be restricted to the cases that do not respond readily to irrigation and sulfanilamide.

(4) One-percent AgNO_3 solution daily or every other day applied with a moistened cotton applicator to the tarsal conjunctiva when it becomes ulcerated and granular. This is used only when the infection has become chronic.

The general treatment consists of sulfanilamide and supportive care. Sulfanilamide is given in doses of 15 grains for every 20 pounds of body weight, divided into six doses and given every four hours. One fourth to one half the 24-hour dose is given on admission. When given subcutaneously a 1-percent solution of sulfanilamide is used: 100 c.c. for every 40 pounds body weight, given every 12 hours. The concentration of sulfanilamide in the blood should be kept above 5 mg. percent. These maximum doses are given until negative eye smears are obtained and the eye is obviously improved. The dosage is then gradually decreased in a period of three days to about one third the original amount and continued on the lowered figure for another 7 to 10 days. This is done to prevent relapse

*From the Department of Medicine, University of Southern California, and the Los Angeles County Hospital.

When acidosis is impending, sodium bicarbonate is given by mouth in the same dosage as the sulfanilamide. To detect impending acidosis, the urine is checked daily with nitrazine paper. Complete blood counts are made daily the first three days and then every third day to discover any idiosyncrasy to the drug.

The three failures were all in infants. The first was a 4-pound infant admitted with a bilateral involvement of 11 days' duration. Negative eye smears were obtained after $1\frac{1}{2}$ days of treatment, and the baby was discharged as cured on the seventh day, after negative eye smears had been obtained on five successive days. Five days after discharge the mother noted that the eyes were beginning to drain again. On readmission both eyes were again positive for the gonococcus. Upon reinstituting treatment, negative eye smears were obtained in $2\frac{1}{2}$ days, and the infection was promptly cured. We are presenting this case as a possible relapse. It may have been a reinfection from the mother.

The second patient was a 4-pound, 2-ounce baby admitted with an involvement of both eyes of a 1-day duration. Negative eye smears were obtained in 24 hours, and thereafter for five successive days. On the seventh hospital day sulfanilamide was discontinued because of vomiting. That day one eye had a relapse. Sulfanilamide was again started and increased to maximum doses, but this time without success. Not until after 77 days of continuous care was the infection finally cured. By that time the cornea was badly scarred. We feel now that the relapse probably could have been prevented had we continued small doses of sulfanilamide for a few days longer.

The third patient was a 6-pound, 4-ounce baby admitted with a bilateral involvement of 7 days' duration. After 3 days treatment the discharge was markedly decreased, requiring irrigations

only once an hour. At that time the sulfanilamide was reduced to one half the original dose. Negative eye smears had not yet been obtained. The eyes promptly became worse. Sulfanilamide was gradually increased to maximum doses, and although the eyes improved, they were not cured. Not until after 47 days was the infection finally stopped. We feel that in this case the blood sulfanilamide was reduced to a low level too soon. This time the end results were more fortunate, however, and both eyes were saved.

SUMMARY

Twenty-one cases of bacteriologically proved gonorrheal ophthalmia were treated with local measures and sulfanilamide. Eighteen responded successfully with a first negative eye smear in an average of two days, and with a local treatment requiring an average of 10 days.

In this group 10 were adults; two were children, five and nine years of age, respectively; and six were infants under 30 days.

In all cases when the cornea was uninvolved on admission, vision was entirely preserved. In no case did corneal perforation occur.

All of the three failures were in infants, of whom two were premature.

CONCLUSIONS

(1) Sulfanilamide is of great value in the treatment of gonorrheal ophthalmia when combined with adequate local therapy.

(2) Best results are obtained when a high blood sulfanilamide concentration is achieved early in the treatment and maintained long enough to secure negative eye smears.

(3) Relapse can best be prevented by continuing sulfanilamide in small doses for 7 to 10 days after the first negative eye smear.

LECTURES ON MOTOR ANOMALIES*

VII. PARALYSES: GENERAL SYMPTOMATOLOGY

A. BIELSCHOWSKY, M.D.

Hanover, New Hampshire

If, in a case of orthophoria, a single muscle becomes paretic, deviation of the paretic eye in the primary position must take place due to the loss of tonus of the paretic muscle, and the intact tonus of all the other muscles. The deviation of the paretic eye in the primary position of gaze will be either manifest or latent, according to the intensity of the paresis and the function of the paretic muscle. A latent or only temporarily manifest deviation results if, for instance, the internal rectus is weakened, since paretic divergence of not too high a degree can be overcome by a convergence impulse. But even a slight paresis of one of the elevators or depressors cannot be kept latent for the primary direction of gaze and with the head in the normal position, because the vertical range of fusion is very small. That is true only of cases of orthophoria. In a case of heterophoria the paretic deviation is modified by the anomalous position of rest—increased or diminished, or even abolished, or made up of various components—as will be shown presently in discussing the palsies of individual muscles.

If the paresis is the only cause of the deviation, the latter will disappear and the former orthophoria will be restored as soon as the paresis is cured; that is, as soon as the paretic muscle has regained its normal tonus. This cannot happen if the paretic deviation is caused not only by the normal tonus of the intact muscles but

also by the development of a secondary contracture of the antagonist of the paretic muscle, due to a change of the former's structure. In such cases a part of the deviation will remain even when the paresis is cured. In any case of typical paresis of a single muscle the angle of deviation increases or decreases according to whether the movement of the eye is in the direction of action of the paretic muscle or of its antagonist. The exceptions to this rule I shall discuss shortly.

The diagnosis of a muscular palsy, can easily be made if the movement of the paretic eye in a certain direction is limited. But in many cases of slight paresis there is no such limitation, because the limits of the ocular movements depend not only on the intact function of the ocular muscles but also to a considerable extent on the fascial check ligaments. In order to reach the normal limits of movement in the various directions a maximum innervation is not necessary. A moderate innervation is enough to bring the eyes to the normal limits, which the check ligaments do not allow to be exceeded, except in cases of paralyzes in which a structural change of the antagonist of the paralyzed muscle has taken place, due to a long-standing secondary contracture. Therefore, even a paretic muscle can bring the eye to the normal limit by means of an excessive innervation. Hence, as mentioned in the lecture on the physiology of ocular movements (Aug., 1938, p. 851), the uniocular field of fixation is of not nearly so great value for the diagnosis of a slight paresis as is the binocular field of fixation or the field of binocular single vision, the limits of which are nearly identical. According

* From The Dartmouth Eye Institute, Dartmouth Medical School. Read before the Seventh Annual Mid-Winter Clinical Course of the Research Study Club, Los Angeles, California, January, 1938.

to Hering's law of the equal innervation of both eyes, a motor impulse must produce a different effect on each eye if one of the muscles executing the bilateral movement is paretic. From this, a considerable limitation of the binocular field of fixation must result, even if both eyes, tested separately, are able to reach the normal limits of movement. The most important signs of the typical palsies—for instance, the difference between the primary and the secondary deviation, and its increase and decrease in looking in the direction of action of the paralyzed muscle or its antagonist—are derived from the aforementioned fundamental law of association of the movements of the eyes.

We speak of primary deviation if the normal eye is fixating. Secondary deviation is the deviation of the normal eye if the paretic one is taking fixation. The difference between the amount of the primary and secondary deviation is a characteristic of paralytic squint in its first and uncomplicated stage. If, for instance, the right eye is turned in at an angle of 10 degrees because of a paresis of its external rectus, while the left eye is looking at an object straight ahead, the latter will turn in at an angle of perhaps 20 degrees or more if it is covered, and the paretic eye is induced to look at the fixation object. The secondary deviation of the sound eye must be greater than the primary deviation of the paretic eye because the paretic external rectus would not be able to turn the right eye at an angle of 10 degrees from its convergent position into the median position by means of an innervation impulse that would bring about this movement in a normal eye. On account of the paresis, a much stronger dextroversion impulse must be given, to which the paretic eye responds with a movement of 10 degrees, while that impulse, according to the law of equal innervation of the two eyes, has the normal effect on the sound

eye so that it moves to the right at an angle of 20 degrees or more. It is easily understood that the more dextroversion is asked of a patient with right abducens paresis, the more will his right eye lag behind the left eye; whereas in levover-sion, in which the paretic muscle does not act as agonist, the deviation will decrease. Finally, in the left periphery of the field of fixation, binocular single vision will be possible, either because in that direction of gaze the right external rectus is completely relaxed also under normal conditions, or the fusion tendency may be able to overcome a slight residue of the paretic deviation by means of a compensating divergent innervation. In concomitant squint there is neither a difference between the primary and secondary deviation nor an increase, or decrease, respectively, of the angle of squint in dexto- and levover-sion, because the two eyes respond equally to the motor innervations.

The characteristic behavior of the paretic deviation just discussed is frequently missed in later stages of pareses. It is not unusual, in a case of abducens-nerve palsy that is quite typical in the beginning, to find that the difference between the primary and the secondary deviation decreases more or less gradually and at last disappears, the deviation thus becoming no longer distinguishable from a concomitant squint or from a divergence paralysis, particularly as the deviation even in looking toward the side of the paralyzed eye increases just as little as it decreases in looking toward the other side. This behavior can be explained in the following manner: If the paresis of the external rectus muscle improves, while a contracture of the internal rectus is at the same time developing, the deviation does not decrease but extends gradually over the whole field of fixation. In spite of the fact that the external rectus has regained its normal function the de-

viation may be maintained by the contracture of the internal rectus. This contracture, if it is only due to an increased tonus of nervous origin, can disappear in the course of time and binocular single vision can be restored in the whole field of fixation. In other cases the contracture becomes permanent by a gradual change of the muscular structure of the internal rectus. Then a concomitant deviation remains, the angle of squint being approximately equal in the whole field of fixation. I am sure that some cases of the latter kind have been mistaken for divergence paralysis, which is to be discussed later.

The amount of the paretic deviation varies individually within wide limits without being proportionate to the degree of the palsy. The photographs of a person with complete abducens-nerve paralysis show a very small primary deviation (A) and an enormous secondary deviation (B, fig. 20). In contrast to this, numerous

Fig. 20 (Bielschowsky). A, primary deviation is very small in spite of complete left abducens-nerve palsy. B, enormous secondary deviation.

patients with slight paresis display a considerable, even a very high, degree of primary deviation from the beginning of the disorder. These remarkable differences are due partly to individual differences in the general muscle tonus. In cases of an unusually small paretic deviation I have found the tendon reflexes unusually weak; on the other hand, in cases of a strikingly high deviation the reflexes have been abnormally increased. Neurologic examination has confirmed my assumption of an unusually weak or, on the other hand, an unusually increased

Fig. 21 (Bielschowsky). A, right abducens-nerve palsy with an extremely high deviation due to a maximal secondary contracture of the internal rectus which keeps the position of the right eye unaltered in spite of a maximal dextroversion impulse, B.

muscle tonus. However, I do not believe that the degree of paretic deviation depends wholly on the general muscle tonus. Possibly the region and the kind of lesion causing the paresis also influence the degree of the deviation. If a lesion in the nuclear region produces paralysis of the external rectus muscle and at the same time affects the fibers transmitting the impulse of inhibition to the internal rectus so that it cannot relax, one may assume that the paretic deviation will be higher than it would be in a case of basal abducens-nerve palsy, in which the inhibitory impulses going to the internal rectus are undisturbed. But this theory requires still further proof by research. Figure 21 A and B shows an extremely high deviation due to a maximal secondary contracture of the antagonist of the paralyzed muscle.

If a general practitioner is consulted by a patient because of a diplopia of paretic origin, he will not infrequently bandage the sound eye, taking it for the paralyzed one. This mistake is due to the patient's constant use of the paretic eye for fixation. There are several reasons why a secondary deviation takes place at

the beginning of the paralysis: First, the vision of the paretic eye is better, the nonparetic eye being amblyopic; second, since separation of the two images is much greater in secondary than in primary deviation, some patients prefer the former because diplopia is the less disturbing the more the double images are

Fig. 22 (Bielschowsky). Unusual habitual position of the head in a case of inveterate abducens-nerve palsy. While holding the chin pressed against his chest (A) the patient has binocular single vision. Pathologic convergence of a high degree occurs when the head is thrown back (B), while the same distant object is fixated.

separated; and, finally, some patients prefer fixation with the paretic eye because it has been dominant since childhood.

Another characteristic to be met with in all cases of pareses where binocular single vision has been retained in a certain part of the field of fixation, is a habitual anomalous position of the head. This is explained by many authors as an endeavor to make up for the function of the paralyzed or weakened muscle; it is obtained by turning the head in the direction of the action of the ocular muscle before it became paralyzed. This explanation is not invariably correct even for the external and internal rectus muscles, much less for the elevators and depressors. True, in most cases of palsy of the abducens nerve there is a habitual turning of the head to the side corresponding to the direction in which the

paretic muscle operates—for instance, to the right in a right abducens paresis, so that the patient looks at an object lying straight ahead with his eyes turned to the left; that is, in the direction in which action of the paretic right external rectus is not called for. Figure 22A shows a patient with abducens-nerve palsy holding the chin pressed against the chest. This position of the head helped the patient to secure binocular single vision, whereas if the head was thrown back (Fig. 22 B) so that the eyes had to look down, the pathologic convergence present in the primary position of the head was increased to a high degree. Why did not the patient turn his head to the side of the paralyzed abducens nerve? Because, due to the long duration of the palsy, secondary contracture of the internal rectus had set in, and the deviation could not be overcome by looking toward the sound side, as was possible in the early stages of the palsy when it was slight and uncomplicated. On the other hand, it is a physiologic law that the elevation of the eyes favors divergence, just as the downward gaze disposes to converge. Both tendencies are due to the mechanical factors influencing the position of the eyes. With few exceptions, in cases of orthophoria one finds latent divergence when the eyes are looking up and latent convergence when they are looking down. Therefore, in cases of slight or moderate convergence in the primary position of the eyes, the deviation may disappear if the patient looks up or lowers the head, whereas it is increased by looking down, or, on the other hand, throwing the head back. The reverse is true in cases of latent or manifest divergence.

The rule under discussion concerning the so-called vicarious rotations of the head proves to be inaccurate in palsies of a single elevator or depressor muscle

much more frequently than in cases of palsy of the external or internal rectus. It is valid only if both elevators or both depressors of one or both eyes are paralyzed; in such cases the head is rotated around the frontal axis—that is, thrown back or depressed. But in pareses of an individual vertical motor, the position of the head is seldom in accordance with this rule. In cases of trochlear-nerve palsy, for instance, the head is usually tilted toward the shoulder of the sound side and at the same time turned around the vertical axis so that the paretic eye is rotated outward. Indeed, in cases of very slight paresis, the position of the head will show only one of the components just mentioned. If the right superior rectus muscle is paralyzed, the face is often turned only to the right, so that the paretic eye is averted. How can such a position of the head effect binocular single vision if an elevator muscle is paretic? The vertical rectus muscles have the greatest influence on the vertical movements when the visual line is averted so that it lies within the muscular plane. The more it moves away from this plane, the more do these muscles lose their influence as elevators and depressors, whereas the influence of the oblique muscles on the vertical movements increases simultaneously in nearly the same proportion. Therefore, a slight vertical deviation due to the paresis of the right superior rectus will disappear if the paretic eye is averted in consequence of the head being turned to the right.

The rule concerning the vicarious rotation of the head must be modified as follows: The patient chooses the least inconvenient position of the head by which the paretic muscle is sufficiently relieved so that binocular single vision can be obtained.

Another symptom of ocular palsy,

called false orientation, is interesting from a scientific point of view, although one can dispense with it for diagnosis. If the patient, while covering his sound eye, is asked to point toward an object situated in front of him or in the field governed by the paralyzed muscle, the finger will point more or less beyond the object and toward the field of action of the paretic muscle. The more the muscle is paralyzed, the more the pointing finger will deviate from the correct position. The origin of this error is obvious: The egocentric (absolute) localization of objects in space is approximately correct as long as the correlation between the innervation of the ocular muscles and its effect is correct; that is, as long as the amount of the actual movement corresponds to that which is intended. But if the right eye is deviated inward, owing to a paresis of the external rectus muscle, and one asks the patient, while covering his left eye, to fixate an object in the median plane of his head, he will have to give a dextroversion impulse, from which he will get the idea that the object to be fixated lies to the right of the median plane. On measuring the error found in the pointing test by a method more exact than this primitive test, one will find that the angle coincides with the secondary deviation; that is, the visual axis of the covered, sound eye is directed to the point at which the paretic eye localizes the fixated object. This behavior is found only in cases of a recent palsy. If the patient is using the paretic eye continually for fixation, the egocentric localization will soon be adapted to the changed relations between innervation impulse and its effect, and the false orientation becomes rectified. But then one will find a different kind of false localization in testing the nonparetic eye while the paretic eye is covered. The patient will point wrongly, but to the

opposite side—that is, to the left—if the normal left eye, which usually is in secondary deviation, is induced to fixate. This kind of false localization is called spastic, in contradistinction to the paretic localization just discussed. Spastic localization is the term for the opposite disproportion between motor innervation and its effect after the innervation in such a case has become adapted to the paresis of the fixating eye, so that it is stronger than is required by a normal

mate information may be obtained about the kind and intensity of the disturbance and so that one may be able to check the reliability of the patient's subjective statements, particularly in the diplopia test. The latter is frequently not necessary for the diagnosis if the objective signs are unequivocal. It is indispensable for obtaining an exact measurement of both the kind and the amount of the deviation in the different parts of the field of fixation; it is the basis for a comparison of

Fig. 23 (Bielschowsky). Diplopia test in a case of left abducens paresis. A, shows the primary deviation while the normal eye is looking through the red glass at the light in the center of the tangent scale. The left visual line is directed to the right number four which, accordingly, is seen to coincide with the red light; the white light being imaged on an eccentric point (α) must appear displaced to the left of the red light at an angle determined between α and the fovea (f). The upper tangent scale in A indicates the displacement as seen by the patient; B, shows the secondary deviation brought about by having the patient's left eye look through the red glass at the fixated light.

muscle for the given amount of movement. Patients with recent paresis suffer more or less from vertigo that is due to the disturbance of the egocentric localization. The patient sees apparent movements of the outlying objects, the double images of which now approach, now separate, according to whether the direction of gaze is outside or inside the field of action of the paretic muscle.

In every case the examination of the objective signs ought to precede that of the subjective symptoms so that approxi-

mate information may be obtained about the kind and intensity of the disturbance and so that one may be able to check the reliability of the patient's subjective statements, particularly in the diplopia test.

The patient is seated with his head in the normal position facing the light in the center of the tangent scale, which, as a rule, is at a distance of 2.5 meters, on a level with his eyes, and in the median plane of his head. A dark-red glass is put, first in front of the normal eye, then in front of the paretic one. The red glass should be so dark that the eye behind it

sees nothing but the colored light. Suppose a patient with a left abducens paresis has the red glass before his right eye. He sees a red light and a white light. Asked on what number the red light lies, he will say that it coincides with the black number four (fig. 23). Now we know that while the right eye is looking through the red glass at the light the visual line of the paretic eye passes through the right number four—the light and number four being imaged on the two foveæ. Since the patient is sitting at a distance of 2.5 meters from the scale and the numbers correspond to arc degrees at a distance of 5 meters, the separation of the double images amounts to 8 degrees. Turning the patient's head first to the left and then to the right, while he is continually looking at the light, so that his eyes go first into dextro- then into levoversion, he will first see the red light coming nearer, then moving farther away from the white light. In this way the behavior of the double images is tested for the whole field of fixation. Without going into all the details, I will discuss only the influence that the change of fixation has on the diplopia in our case. If the red glass is put in front of the left (paretic) eye the red light will appear on the red number 6. Thus there is again uncrossed diplopia, but the separation of the double images has increased to 12 degrees. This increase is due to the fact that it is the secondary deviation that has just been measured. It is to be borne in mind that in using the red glass or the Maddox rod in the diplopia test and asking where the red light is seen, the fixating eye is the one in front of which the red glass has been put. If the patient with a left abducens paresis is questioned, he will say that the tangent scale is displaced to the left as indicated by the upper scale in A (fig. 23), while the red glass is being held before the

right eye; whereas, the scale appears in its right place if he has the red glass before his left eye. The different localization will be understood if one considers that while the sound eye is looking through the red glass, the principal visual direction in which the foveal images—namely, the red light as well as the right number four—are localized, lies in the median plane of the head. If the right number four appears in the median plane the whole tangent scale must, accordingly, appear displaced to the left at an angle of 8 degrees. On the other hand, if the left (paretic) eye is looking through the red glass at the light, it will be seen lying on the left number six, to which the right visual line is directed. Now the visual direction in which the two foveal images appear does not coincide with the median plane because the two eyes are held in the present position by a voluntary levoversion impulse, which is required to bring the normal eye from the primary position to a levoversion of 12 degrees. Figure 24 shows crossed diplopia due to a paretic divergence tested on the tangent scale in the same way as has been described for uncrossed diplopia.

The behavior of the diplopia in the different kinds of pareses may be summarized as follows:

1. Uncrossed diplopia points to a deficiency of one or several muscles with an abverting component, while crossed diplopia points to a deficiency of muscles with an adverting component. In the former group the visual lines converge; in the latter group they diverge.

2. Increase of the lateral distance between the double images in dextroversion is due to a paresis of a dextrovertor of that eye to which the image farthest to the right belongs, that is, the right external rectus if there is uncrossed, the left internal rectus if there is crossed diplopia.

3. Lateral distance is frequently influenced by vertical movements of the eyes since elevation favors a divergent, depression a convergent position of the eyes, due to anatomico-mechanical factors. Hence, crossed double images will, as a rule, move farther apart in the upper, and approach each other in the lower part of the field of fixation, while uncrossed double images will show a de-

crease, while an oblique muscle is concerned if the increase of the vertical divergence is connected with the adversion and the decrease with the abversion of the paretic eye. This behavior is due to the fact that the vertical recti or the oblique muscles act at their best as vertical motors according to whether the eye is turned out, or, on the other hand, turned in, so that the visual line either coincides with or is

Fig. 24 (Bielschowsky). Crossed diplopia due to a paretic divergence. A, shows a primary deviation of 8 degrees while the normal right eye is looking through the red glass at the light, while in B the secondary deviation (12 degrees) is brought about by the transition of the fixation from the right to the left (paretic) eye.

crease of their separation in the lower, an increase in the upper half of the field. A small minority of cases presents the reverse behavior.

4. Vertical diplopia with an increasing separation in elevation points to a paresis of one or both elevator muscles of that eye to which the upper image belongs; while the vertical diplopia which increases when the gaze is lowered, is to be attributed to a paresis of one or both depressors of the eye with which the lower image is seen.

5. Vertical divergence increasing in that lateroversion by which the paretic eye is turned out, and decreasing when looking to the opposite side, points to a paresis of one of the vertical recti mus-

cles, while an oblique muscle is concerned if the increase of the vertical divergence is connected with the adversion and the decrease with the abversion of the paretic eye.

6. If the vertical separation of the double images is combined with a minor horizontal component that does not show the characteristics of a paresis of an internal or external rectus, the lateral deviation is not a decisive factor in the analysis of the paretic disturbance, because rather frequently a nonparetic exophoria or esophoria becoming manifest if fusion is broken by the paretic vertical diplopia, may compensate or even overcompensate the slight horizontal deviation caused by a paresis of one of the vertical motors. Thus, for instance, in 25 percent of trochlear palsies one does not find an

uncrossed beside the vertical diplopia, due to the absence of the abverting component of the oblique muscle, but either no lateral separation at all, or even a crossed separation in cases in which an exophoria, latent before the onset of the paresis, has now become manifest. It goes without saying, that the vertical separation of double images also may be due to a nonparetic hyperphoria that has become manifest after the appearance of a paresis of a lateral muscle.

7. An obliquity of one or both of the double images shows that the physiologic parallelism of the corresponding retinal meridians is lost, a phenomenon suggesting that the balance between the muscles with antagonistic rotary components is disturbed. In order to find out whether the obliquity is due to a disclination (extorsion) or conclination (intorsion) of the vertical meridians, the double images should be examined, not in the old-fashioned manner with a candle for fixation, but with a horizontal object; for instance, with the horizontal arm of the tangent scale. The obliquity of the two images of a vertical object like a candle looks quite different according to whether there is, besides the vertical separation, homonymous or crossed diplopia. In spite of the same paretic disclination, the two images (fig. 25) of a candle will converge or diverge upward according to whether there is homonymous or crossed diplopia; in this way a mistake in diagnosis can arise. It is easy to avoid this mistake if one uses a horizontal object in testing for vertical combined with lateral diplopia. In any case of trochlear-nerve palsy, for instance, the paretic disclination makes the double images converge to the paretic side, whether there is homonymous or crossed diplopia besides the vertical separation.

From the obliquity of the double images one can infer only that there is either

an abnormal disclination or conclination of the vertical meridians, because of a deficiency of muscles with an inward, or, on the other hand, an outward component. But one does not know which eye is the paretic one, since some patients will see the images aslant that belong to the nonparetic eye; while in other cases both

Fig. 25 (Bielschowsky). Different appearance of the double images of a vertical and of a horizontal object in trochlear-nerve palsy according to whether there is, besides the vertical separation, homonymous or crossed diplopia. Though the paretic extorsion is the same in either case, the two images of a vertical object will converge or diverge above, whereas the two images of a horizontal object in such cases will always converge to the paretic side.

images will appear oblique. The former will occur if the paretic eye, being dominant, is used ordinarily for fixation. Then a horizontal contour will appear horizontal to the paretic eye although it is imaged on an oblique meridian, while the nonparetic eye will see that contour aslant despite the fact that its image lies in the horizontal meridian; for as long as the localization of the images of the two eyes relative to each other is dependent on the innate sensorial correspondence, images lying on noncorresponding meridians are localized in different planes deviating from each other by the angle at which those noncorresponding meridians deviate from each other. Since the egocentric localization of outlying objects is not based on innate conditions but acquired during life by daily experiences, it can be adapted to abnormal conditions.

A patient with trochlear palsy, as a rule, will see—while the normal eye is covered—the horizontal and vertical contours of a room as they are, since he knows from experience that, for instance, the contours of the walls or the doors are horizontal and vertical. But if he is examined in a dark room where he sees nothing but a faintly glowing thread, he will see it with the paretic eye either vertical or horizontal only if the position of the thread corresponds to the oblique position of the vertical or horizontal meridian of that eye.

In typical pareses of a vertical motor one knows from the aforementioned data of the investigation, particularly from the fact that the vertical divergence increases either in the upper or lower half of the field of fixation, whether an elevator of the right, or a depressor of the left eye is paralyzed. The obliquity of the image belonging to the paretic eye coincides with the direction in which the horizontal meridian would be rotated by an isolated action of the paretic muscle. A patient

with a right-trochlear-nerve paresis, for instance, will see the left end of the lower image of a horizontal contour tipped downward; that is, in the same direction as the horizontal meridian of the right eye would be tipped by an isolated action of the right superior oblique. If such a paresis belongs to those cases in which the paretic eye is used for fixation, the lower image will be seen horizontal, while the right end of the upper image, seen with the nonparetic eye, is tipped down. In either case the right ends of the double images will converge, pointing to a meridional disclination if the lower image is seen with the right eye, while convergence of the left ends would point either to disclination if the lower image belonged to the left eye, or to condination if it belonged to the right eye.

Further details of the behavior of the double images in the different parts of the field of fixation, as well as with the patient's head in different positions, will be mentioned in the discussion of the pareses of the individual muscles.

RESULTS OF VITAMIN-D-COMPLEX TREATMENT OF KERATOCONUS*

PRELIMINARY STUDY**

ARTHUR ALEXANDER KNAPP, M.D.

New York

In previous communications¹ Blackberg and I described the consistent production of keratoconus in dogs and rats fed a vitamin-D-deficient, low-calcium diet. The eyes of some of the dogs were enucleated and examined microscopically.

Because of the findings in these specimens, it was thought advisable to treat patients suffering from keratoconus with a vitamin-D and calcium diet.

Eleven patients (18 eyes) were included in this study. Seven had bilateral involvement. Three had a right keratoconus and one a left. The degree of conicity varied from the almost imperceptible to the very marked, with rupture of the posterior corneal layers and central opacity.

Each of the patients was given 60 drops of viosterol² after breakfast. More recently however, up to 200 drops have been prescribed. The calcium, taken before the meal, varied with the milk intake. If a patient drank one quart of milk a day, one Mineral Mixture Tablet was given. For each glass less than one quart, two tablets were ordered. So, if a patient drank no milk, he would receive nine tablets daily.

These patients have been observed for varying periods of time, from three

Read before the New York Academy of Medicine, Section on Ophthalmology, December 20, 1937, and the North Jersey Academy of Medicine, Section on Ophthalmology, May 9, 1938.

**The subject matter of this paper is substantially that presented in the June, 1938, issue of The Journal of The American Medical Association. The charts are presented here for the first time.

months to three years. It will be noticed that in every case there was subjective and objective improvement. Subjectively, the vision improved. Objectively, the improvement was seen by macroscopic, corneal microscopic, cycloplegic refraction, and ophthalmometric examinations. Recently, to be more accurate, plaster-of-Paris casts of the eyes have been used to measure the height of the cones before and after treatment. Twelve molds of six eyes, replicas of the corneas of the eyes of three patients before treatment and three to six months after, were carefully measured by Professor Carlos de Zafra of the engineering department, assisted by Professor Louis Granath of the physics department of New York University. All of the six later molds showed a flattening of the cone. The height of five of these was reduced. One manifested an apparent increase in the height of the cone, but this may not be an actual increase; for it might be mentioned that these cones were measured by taking a chord of the anterior segment of the eyes, using a fixed base line. With shrinkage of the cornea, the base line included a greater portion of the anterior segment. Actually, therefore, the sixth mold also may have a reduced cone. Practically, this may be seen after examining the eleventh patient. Three years ago she presented herself, with palpebral fissures approximately equal in their vertical meridians. In the right eye she had an advanced keratoconus; in the left, a mild myopia. She has been under treatment during this time. For the past year she has been conscious of a ptosis of her right upper lid.

TABLE 1
DATA ON VITAMIN THERAPY IN KERATOCONUS

Name	Age	Sex	Race	Degree of Keratoconus	Improvement with Vitamin-D-Complex Treatment	
					Subjective	Objective
1. N. L.	39	M.	W.	Marked in O.D. with central nebula. Mild in O.S.	Driving a car at night is much simpler. Spider-web effect of lights not so disturbing. Pins in bowling alley now distinct. Eyes not irritated. Headaches much relieved. Without treatment, symptoms worse.	<p>Height of corneal apex from common base line:</p> <p>Molds: Before therapy After 6 mos. Difference</p> <p>O.D. .1478" .1448" 0.0762 mm.</p> <p>O.S. .1262" .1014" 0.6292 mm.</p> <p>Cycloplegic refraction:</p> <p>Before therapy, O.D. -11.00 D. cyl. ax. 40°</p> <p>O.S. - 5.75 D. cyl. ax. 140°</p> <p>After 6 mos., O.D. - 9.50 D. cyl. ax. 40°</p> <p>O.S. + .50 D. sph. ≈ -5.75 D. cyl. ax. 140°</p> <p>Corneal microscope—thicker central cornea.</p> <p>Macroscopically—apex of cone less prominent.</p> <p>Vision of O.D. improved from 7/200 to 15/100+ in six months. O.S. from 15/20- to 15/20 with correction: O.D. from 15/100+ to 15/50- O.S. from 15/15- to 15/15</p>
2. F. C.	23	F.	W.	Marked in O.D. Moderate in O.S.	Vision definitely clearer.	<p>Height of corneal apex from common base line:</p> <p>Molds: Before therapy After 3 mos. Difference</p> <p>O.D. .1359" .1307" 0.13098 mm.</p> <p>O.S. .1356" .1154" 0.51308 mm.</p> <p>Corneal microscope—denser cone.</p> <p>Macroscopically—cones lower and flatter.</p> <p>Vision O.D. without correction 20/100; after 3 mo. 20/50-</p> <p>O.S. without correction 20/100; after 3 mo. 20/50</p>
3. S. S.	37	M.	W.	Marked in O.U.	"Eyes altogether different now. Eyes used to shake, and almost blind. They are not so weak any more." Sees and picks up pickles with greater ease. Clock observed at further distance.	<p>Height of corneal apex from common base line:</p> <p>Molds: Before therapy After 3 mos. Difference</p> <p>O.D. .1206" .1104" 0.25908 mm.</p> <p>O.S. .1296" .1365" 0.17526 mm.</p> <p>Corneal microscope—hyperbolic curves less acute.</p> <p>Macroscopically—cones flatter, with radius of curvature more uniform.</p>
4. A. D.	25	F.	W.	Marked in O.D. with central macula Mild in O.S.	Doesn't bump into doors and things now. Doesn't get things in eyes. Able to play cards now. Letters are more distinct—previously had lines running up and down. Pictures are not "cockeyed." Eyes are not "stiff." Formerly could not read nor sew at night with any comfort. Easier to dance.	<p>Cycloplegic refractions:</p> <p>Before therapy, O.D. unimproved</p> <p>O.S. +.25 D. sph. ≈ -1.75 D. cyl. ax. 105°</p> <p>After 10 mos. O.D. unimproved</p> <p>O.S. +1.00 D. sph. ≈ -2.00 D. cyl. ax. 95°</p> <p>Corneal microscope—thicker central cornea.</p> <p>Macroscopic improvement—lower and flatter cones.</p> <p>Vision O.S. with correction 20/30-; after 10 mo. 20/20.</p>
5. A. S.	60	M.	W.	Marked in O.U. with corneal maculae.	Vision improved. No more pain in eyes.	<p>With correction</p> <p>Before, O.D. -2.00 D. sph. ≈ -.50 D. cyl. ax. 75° = 20/70-</p> <p>O.S. -1.50 D. sph. ≈ -1.00 D. cyl. ax. 180° = 20/70-</p> <p>After 6 mos., O.D. -4.50 D. sph. ≈ +9.00 D. cyl. ax. 172° = 20/50</p> <p>O.S. -10.50 D. sph. ≈ -5.50 D. cyl. ax. 75° = 20/50</p> <p>Corneal microscope—thicker membrane.</p> <p>Macroscopic improvement comparatively marked.</p>

TABLE 1—Continued

Name	Age	Sex	Race	Degree of Keratoconus	Improvement with Vitamin-D-Complex Treatment	
					Subjective	Objective
6. M. B.	32	M.	W.	Normal O.D. Mild in O.S.	Sees better. Eyes less tired.	Vision of O.S. improved from 10/200 to 20/100 in 8 mos. Cycloplegic refraction: Before, -3.00 D. cyl. ax. $70^{\circ}=15/200$ After, $+ .75$ D. sph. ≈ -2.50 D. cyl. ax. $75^{\circ}=20/70$ Corneal microscope—denser membrane. Macroscopically improved, with flatter cone.
7. V. P.	37	F.	W.	Mild in O.U.	Vision clearer and better. No more distortion of objects, as believing that a man crossing the street was riding a bicycle, or mistaking a lemon for an orange. Does not "squint" now and eyes do not tear. Does not have headaches after movies now. Symptoms returned when patient was without medication for 8 weeks.	Vision O.U. improved from 20/200 to 20/100 in 7 mos. Cycloplegic refraction: Before, O.U. -1.00 D. cyl. ax. $90^{\circ}=20/70$ After, O.D. $+ .25$ D. sph. ≈ -1.00 D. cyl. ax. $40^{\circ}=20/40$ O.S. $+ .50$ D. sph. ≈ -1.00 D. cyl. ax. $90^{\circ}=20/30$ Corneal microscope—denser central membrane. Macroscopic improvement.
8. C. P.	20	F.	W.	Mild in O.D. with leucoma (esotropia and lens opacity)	Painful and tearing eyes improved. Vision slightly better.	Cycloplegic refraction from -10.00 D. sph. to -8.00 D. sph. ≈ -1.00 D. cyl. ax. 15° , in six months. Corneal microscope—thicker central membrane. Macroscopically—less prominent and flatter cones.
9. M. C.	43	M.	W.	Mild in O.D. Moderate in O.S., with central nebula	Vision much clearer. Faces and objects more distinct. Worse without medication.	After 2 years, ophthalmometer shows astigmatism of O.D. to be more regular. Corneal microscope—thicker central membrane. Macroscopically—less prominent and flatter cones.
10. E. W.	29	F.	W.	Marked in O.D., with central macula. Moderate in O.S.	Vision improved. People in moving pictures much more distinct. Able to sit further back in theater. Reading and sewing done with greater ease.	Vision improved O.D. 5/200 to 15/200 in 7 mos. O.S. 15/200 to 15/70 Cycloplegic refraction: Before, O.D. unimproved 5/200 O.S. -1.00 D. sph. ≈ -7.00 D. cyl. ax. $85^{\circ}=15/100$ After 7 mos., O.D. -1.25 D. sph. ≈ -8.50 D. cyl. ax. $100^{\circ}=15/100$ O.S. $-.25$ D. sph. ≈ -7.00 D. cyl. ax. $85^{\circ}=15/50$ Corneal microscope—thicker central membrane. Macroscopically—cones less prominent and flatter.
11. B. M.	34	F.	W.	Marked in O.D., with central macula. Absent in O.S.	Drooping of right upper lid.	Pressure bandage and simple iridectomy of no avail. After 3 years' therapy conus has diminished greatly. There is a ptosis with a narrowed palpebral fissure. The cornea is smaller, with an excess of tissue heaped up in the central vertical meridian, over the former site of an epithelial cyst. Corneal microscopy—thicker central cornea.

In all probability, this ptosis is due to a shrinkage of the cornea, as well as of the sclera. For, as will be shown in a later paper, the sclera, too, may shrink.

CONCLUSION

From the foregoing data, it may be concluded that the vitamin-D complex has a definite place in the therapy of kerato-

conus. Further research will determine its proper position in the therapeutics of this condition.

Miss Diana Shrage of the New York Eye and Ear Infirmary assisted in this work. Products used in the study were supplied by the Mead Johnson Company of Evansville, Indiana.

PROBLEMS IN THE DIAGNOSIS OF ABSCESS AND TUMOR OF THE ORBIT*

WILLIAM L. BENEDICT, M.D.
Rochester, Minnesota

Whenever it becomes necessary to determine whether a pathologic condition within an orbit is due to abscess or tumor, consideration of certain factors becomes of decisive importance. The problem of distinguishing between these two pathologic processes is complicated by the fact that the outstanding signs and symptoms, which are common for both conditions, are also found in aneurysm of the ophthalmic artery, in cavernous-sinus thrombosis, in pseudotumor, and in orbital complications of Hodgkin's disease, tularemia, Parinaud's conjunctivitis and other local or systemic diseases, or following trauma. Obviously the diagnosis is not always clear by inspection alone. The history of the onset and progression of symptoms is of equal importance to the status prior to the beginning of noticeable changes and to the physical findings of a corroborative nature. The differentiation hinges on the history, physical findings, functional changes, re-

sponse to treatment, and, finally, on histopathologic examination.

It is not often that one is called on to utilize all or even most of these factors to distinguish between orbital abscess and orbital tumor. In the majority of cases the evidence in favor of one or the other condition is so marked that only one probable diagnosis can be substantiated. Acute cellulitis that subsides with the formation of a palpable, fluctuant mass points only to an accumulation of pus and débris. The chance that any other pathologic condition may also be present is unthinkable rare, although the possibility must not be lost sight of, because the unfortunate incising of an aneurysm under the impression that an abscess was being drained has led more than one surgeon to regret his action.

Acute cellulitis may arise from localized periostitis within the orbit, and, when situated along the roof of the orbit, the differential diagnosis becomes of importance because of the proximity of such a lesion to the brain. Most suppurative lesions of the orbit, whether originating in periostitis, invasion from infected

* From the Section on Ophthalmology, The Mayo Clinic. Read before the meeting of the Pacific Coast Oto-Ophthalmological Society, Victoria, British Columbia, June 21 to 24, 1938.

sinuses, or from introduction of foreign bodies from without by penetrating injuries, tend to become walled off by a surrounding infiltration and gradually work toward the orbital outlet, where they point in the lid, open, and become fistulous tracts. The anatomic structure of the orbit permits three potential spaces for abscess formation: (1) between the bone and periorbita, particularly along the roof; (2) between the periorbita and the muscle cone, and (3) within the cone itself. Of these potential spaces, orbital abscesses are found most frequently in the one first mentioned, for the reason that most of them are due to lesions that invade the orbit from without; that is, from the frontal or ethmoidal sinus. Consequently, in the absence of localizing signs, exploration of the orbit for relief of abscess should be directed toward the roof between the bone and the periorbita. Incision should be made through the skin of the lid just beneath the brow and the superior orbital margin.

It is fortunate that neoplasms of the orbit do not break down into cystic masses and that chronic inflammatory lesions of the orbit seldom take on malignant characteristics. With the exception of mixed tumors of a low grade of malignancy and some of the mixed basal-cell and squamous-cell carcinomas, neoplasms of the orbit, both primary and metastatic, increase in size along directions of least resistance and without signs that are indicative of abscess formation. However, in a case of extensive melanoma of the orbit which required exenteration, I found that the posterior third of the orbit contained only a thick black fluid with degenerated tissue débris, in many respects the complete counterpart of a cold abscess. This patient had deeply pigmented pharyngeal, nasal, and buccal mucous membranes without characteristic signs of malignancy and is alive and

well more than 10 years after the exenteration.

Exophthalmos is the outstanding indication of increased mass within the orbit and is present as the first sign in most diseases of the orbit. The bony walls of the orbit offer resistance to the expansion of a new growth or abscess, to an increase in the size of an aneurysm, or to the edema of orbital tissues in goiter; as a result, the membranous anterior wall gives way, permitting the eyeball to move forward. There are two elements in exophthalmos that are significant, the rate of progress and the lateral or vertical displacement.

If fluid is injected into the orbit, the eyeball moves slowly and steadily straight forward and becomes fixed and immobile. The dispersion of the injected fluid within the orbit is not impeded, and the eyeball moves forward without lateral displacement. I have seen one case of traumatic arteriovenous aneurysm of the orbit in which the history of the development of the exophthalmos was very important. A child's right orbit was injured by a pitchfork tine when the child slid down a haystack. On examination at the clinic several days later, the eyelids were markedly edematous and discolored, the conjunctiva congested and chemotic, the eyeball pushed forward and immobile, and the cornea clear; vision was 6/10 without glasses. There was little pain or tenderness. A slight thrill synchronous with a slight bruit pointed to arteriovenous aneurysm, but whether they were the result of direct injury or of subsequent erosion through suppuration was the question. The child had no fever and the blood count was normal. The most significant factor, to my mind, however, was the statement in the history that, immediately after the injury, the proptosis of the eyeball and swelling of the lids was as great as it had been at any time since, the only change in the picture having

been the congestion of the conjunctiva and discoloration of the eyelids which developed slowly afterward. As there were no definite signs of infection, exploration was not indicated. A mild pressure bandage worn for a few weeks was sufficient to bring about complete recovery. The proptosis was due to extensive hemorrhage from a wounded orbital vessel, probably an artery, because pulsation of the proptosed eye was visible for several weeks. This seems to indicate that fluid within the orbit, whether from an external or internal source, if unimpeded by artificial barriers will become evenly dispersed and produce proptosis without lateral displacement of the eyeball.

The contrary condition is found in the case of very slow-growing tumors of the bony walls of the orbit. Osteomas do not grow in the direction of least resistance. They invade the orbit or the cranial cavity, or the bony framework of the face or head, without regard to resistance. Osteomas of the orbit arise within a paranasal sinus and are always covered by a mucous membrane continuous with the lining of the sinus of origin; by continuous expansion the cavity becomes filled with a bony tumor. Barriers, of whatever nature, are eroded by pressure of the advancing osteoma, but the adjustment is so slow that external deformity is a late manifestation and proptosis is seldom extreme. Lateral displacement of the eyeball is quite marked, however, if the osteoma is in the anterior third of the orbit, less so if the tumor is in the middle or posterior third. Furthermore, a slow rate of growth of either a tumor or an abscess permits adjustment within the orbital tissues, so that proptosis develops only after the mass has reached considerable size, and then it progresses less rapidly.

For a given amount of increased mass within the orbit, proptosis is developed

in proportion to the rate of increase in the mass. From this generalization one may infer that the size of a tumor or abscess cannot be estimated with even fair accuracy by the extent of proptosis alone, and that the duration (or age) of a slow-growing tumor can be estimated only approximately by the onset of proptosis. Tumors and abscesses act in a similar manner to produce exophthalmos, and differentiation of the two conditions cannot therefore be made on the basis of the proptosis alone. This applies particularly to cold abscesses and localized inflammatory masses due to tuberculosis and to syphilitic periostitis and gumma.

Rapid swelling of the tissues of the orbit, accompanied by proptosis, pain, tenderness, and loss of mobility of the eyeball in a person with arthritis, gout, or other constitutional disorders of metabolism, may be suspected to be cellulitis of the orbit; this may lead to abscess or to localized hemorrhage accompanying thrombosis of an orbital vein. Vascular accidents occur along the sheaths of the optic nerve and give rise to retinal venous engorgement and edema of the disc and adjacent retina without producing scotomas or other visual impairment. Also, along the tendons and, indeed, throughout the orbit, hemorrhages frequently appear and are absorbed without attracting attention; subconjunctival hemorrhages are as a rule no more significant. Hemorrhages within the orbit are seldom of importance either as primary lesions or as complications of injury. A ruptured sacculated aneurysm will heal spontaneously with the aid of a compression bandage.

Exophthalmic goiter frequently is a most difficult condition to demonstrate and is therefore one of the greatest stumbling blocks to a correct diagnosis of orbital tumor. Exophthalmos is present in only about a third of the cases in which

there is moderate elevation of the metabolic rate; it is frequently a delayed sign of the disease, coming on only after the metabolic rate has receded and after other signs of the disease have disappeared. Exophthalmos may appear as the only sign of toxic goiter, and as it may appear in one eye only, the cause of the exophthalmos may be in doubt. Operation on the orbit under such conditions has been carried out in a number of cases but with negative results. On finding no pathologic changes in the orbit, the condition in such cases has been erroneously classified as "pseudotumor" of the orbit. That name does not apply to such conditions as are found in goiter and should be reserved for a particularly definite pathologic condition which I have described elsewhere. Not many cases of exophthalmic goiter will be missed if the basal metabolic rate of all persons with noninflammatory exophthalmos is determined. An increased metabolic rate is pathognomonic of hyperthyroidism, although a low rate is not sufficient evidence to reject a diagnosis of previous hyperthyroidism. The sequelae of hyperthyroidism, particularly exophthalmos without an increased metabolic rate, must not be overlooked.

I am inclined to believe that, in the past, the condition has in many cases been erroneously looked upon as syphilitic because the proptosis and swelling responded to treatment with iodides. The diagnosis of syphilis in orbital disease has waned, however, as biologic tests for syphilis have become more reliable and as means of recognizing disturbances of the glands of internal secretion have become more widely known. The therapeutic use of iodides has taken on a deeper significance as well. A trial of medical measures, probably combined with the use of irradiation, will bring about satisfactory results in a large number of suspected

cases of orbital tumor and abscess. Only the etiology and true nature of the process will remain in obscurity.

The use of roentgenograms for the diagnosis of orbital tumor is now universal; at least in no case would roentgenography be omitted. The interpretation of roentgenograms, however, requires skill and wide experience. We have all seen the folly of operating solely on the basis of the roentgenographic evidence and we have all felt keen disappointment at the failure of some suspected condition to show up in the roentgenogram. Negative roentgenograms are often dangerously misleading, particularly in cases of meningioma and hemangioma, and a sense of false security may be engendered by a poorly made or misinterpreted roentgenogram. In only one condition do I have complete confidence in the roentgenogram, and that is in osteoma. A diagnosis of osteoma in the face of negative roentgenograms cannot be justified, yet I have known this error to be made many times. The reason for the mistake is obvious. A soft-tissue tumor or a cyst situated anteriorly so that it can be palpated near the rim of the orbital outlet will usually seem to be quite hard, unyielding, immovable, and not tender. The continuity of bone seems quite evident and the tumor seems definitely limited. Such tumors are usually encased in a tight-fitting, tense capsule, and while inside they may be of a soft consistency or even fluid, they are unyielding to pressure and are immovable; this gives the impression that what is felt is a bony tumor. If a roentgenogram fails to show definite bony growth it is not likely that an osteoma is present. Palpation is not trustworthy evidence on which to base a diagnosis of orbital tumor.

What I have considered thus far refers to occult orbital tumors or abscesses. The same general conclusions may be applied

if I should include cysts, mucocoeles, meningocoeles, and pyocoeles. Not only must the presence of any of these pathologic conditions be diagnosed by indirect evidence, but their situation, size, age or duration, and histopathologic nature must be inferred. The clinical picture is a composite one of all the signs and symptoms that can be elicited, viewed in the light of a well-derived history. If the diagnosis is not clearly established, the indications may point to medical treatment, watchful waiting, and consultation, but seldom to surgical exploration. Aspiration may be employed under proper safeguards, but operative interference is justified only on clear-cut evidence of definite pathologic changes or after failure of relief by nonsurgical treatment, and then only under strictly aseptic precautions. So many patients with suspected occult tumor have been entirely relieved by nonsurgical measures, with such little risk of permitting a bad condition to grow worse, that I advise, teach, and practice conservatism in such cases.

As against the occult tumor of the orbit there is the superficial cancer of the eyelids or conjunctiva that invades the orbit by direct extension. In these cases there may be no doubt of the diagnosis, but it may be difficult to determine whether and to what extent the orbit has become involved. Basal-cell cancer of the lid does not metastasize but grows by direct extension, usually toward bone. Originating in the deeper layers of the skin, the malignant growth extends in all directions with sloughing or ulceration only on the surface. As the advancing edge of the rodent ulcer breaks down and the part first affected tends to heal, there is a deeper process that does not break down and heal but continues to send fingerlike projections through the indurated substrata. When bone is reached, extension proceeds rapidly beneath the periosteum, the tumor

becomes fixed, and the situation becomes grave. A fixed or immobile basal-cell epithelioma is a potential orbital tumor and must be dealt with accordingly.

Compared to basal-cell cancers, squamous-cell cancers are doubly dangerous because of their greater malignancy and tendency to metastasize. I have not been impressed by the reputed healing of superficial basal-cell cancers by the application of mild heat or violet rays. Such measures may induce surface healing, and for a time the result may seem satisfactory, but recurrences are the rule. Like an iceberg, about four-fifths of the mass is below the surface, and the deeper cancer cells are not obliterated. Basal-cell carcinomas are of a low grade of malignancy and may lie dormant or grow imperceptibly. They seem to be more formidable when situated near the canthi, and I believe it is because, in these regions, they have easier access to bone. When they do invade the orbit, only extensive exenteration will arrest them.

Another difficult problem in the diagnosis of orbital tumor is presented by the melanomas. I shall not speak of the intraocular melanomas, as their significance is obvious. Pigmented nodules of the lids and lid margins and of the caruncles are mostly benign nevi and comparatively seldom take on malignant characteristics. On the conjunctiva, however, pigmented lesions of any size are abnormal and very frequently they undergo malignant change even after many years of quiescence. Melano-epitheliomas of the conjunctiva grow fairly rapidly and give rise very early to hematogenous metastasis. From a single pigmented spot in the conjunctiva, multiple areas will rapidly arise nearby, being deeply pigmented from the start. The tendency to direct extension into the orbit is almost negligible. Seldom does one see a mass of proliferation come from the conjunctiva; instead,

there will be seen a widespread pigmentation with congestion and thickening of the conjunctiva resembling a low-grade inflammation. There are no lymphatic structures within the orbit and the lymphatics of the lids and conjunctiva drain away from the orbit, which accounts for the low incidence of orbital involvement and the high incidence of metastasis to other parts of the body. At biopsy it is well to bear in mind that local recurrences and remote metastatic lesions of melanomas primary within the eyeball frequently are nonpigmented.

A condition of the orbit characterized by mild swelling of the lids, mild chemosis, and exophthalmos, all slowly progressive without pain or fever, is often-times referred to as "pseudotumor of the orbit." The reasons for the appearance of the signs of intraorbital disease do not become clear, and one is confronted with the necessity of remaining in ignorance of the true condition while watching its progress, or of exploring the orbit. Obviously, paracentesis and aspiration are useless. Biologic tests for syphilis and tuberculosis give negative results, and roentgenograms of the head are negative. Tenderness on palpation may be present or absent, but definite signs of abscess or

tumor are wanting. When the orbit is thoroughly explored, a tumor, or abscess, or cyst is not found. The pathologic report on the tissue removed is "chronic inflammation." The orbit is closed and the condition subsides. Such a history may apply to several of the comparatively rare conditions of the orbit: chronic inflammatory pseudotumor, Mikulicz's disease, lymphoma, vascular tumors, leukemic and pseudoleukemic tumors, the chloromas, and inflammation of tuberculous character.

The chances of obtaining satisfactory information from biopsy would hardly justify the procedure, as only thorough digital exploration would reveal a mass in the posterior third of the orbit. Unless exploration can be thorough and unless adequate surgical correction can be carried out immediately, surgical intervention should not be attempted.

In the absence of corroborating constitutional signs of systemic disease, so long as the etiology of pathologic changes in the orbit remains in doubt I would urge observation under whatever nonsurgical form of treatment would seem to offer the best results until a definite distinction between malignancy and inflammation can be made.

NOTES, CASES, INSTRUMENTS

NEVUS FLAMMEUS AND ARRESTED HYDROPHTHALMOS

WINDSOR S. DAVIES, M.D.
Detroit, Michigan

P. S., aged 42 years, a Lithuanian laborer, came to the North End Clinic on March 14, 1938, complaining of difficulty in obtaining gainful employment due to poor vision in the left eye. He stated that he never remembered having been able to see more than shadows out of his left

Fig. 1 (Davies). Nevus flammeus and arrested hydrophthalmos.

eye and that a birthmark on the left side of his face had always caused him considerable embarrassment. The past history was essentially negative except for the duration of the present complaint. There was no history of epileptiform seizures.

Examination revealed a nevus flammeus involving the nose, upper lip, and cheek, and upper and lower eyelids on the left side, which gradually faded off in the temple region as shown in figure 1. The left eye was divergent about 15 de-

grees as measured in the Priestley-Smith manner. Vision was 20/20 in the right eye and only the perception of light in the left eye. Both the external eye examination and the fundus study were essentially negative on the right side. The left eye was slightly larger than the right. The conjunctiva was definitely involved by the nevus with considerable dilation of the anterior ciliary arteries. About the limbus there was increased vascularity with many fine bulbous enlargements of the vessels. The cornea of the right eye measured 11 mm. in diameter and of the left 13 mm. The anterior chamber and iris were negative. Pupils were equal and active. Fundus examination of the left eye revealed the disc to be oval vertically, markedly atrophic, and with deep glaucomatous cupping. The arteries and veins were small. The macula was negative. Intraocular tension (Schiotz) measured 19 mm. Hg in the right and 20 mm. in the left eye. Prolonged dilation over a period of two weeks with atropine sulphate 1 percent did not increase the tension. Fields were normal in the right eye but were not obtainable in the left due to poor vision. No evidence of angioma of the choroid was seen. Roentgenograms of the skull were negative. The blood Kahn test for syphilis was negative. The physical and neurological examinations were otherwise negative.

This is a case of unilateral nevus flammeus associated with glaucomatous cupping of the disc, atrophy of the optic nerve, increase in size of the cornea and eyeball without increase in intraocular tension. This case, it would seem, could be classified as one of arrested hydrophthalmos.

TREATMENT OF TRACHOMA WITH SULFANILAMIDE

A PRELIMINARY REPORT*

MAX HIRSCHFELDER, M.D.

Harrisburg, Illinois

According to findings of Loe (which were confirmed by Richards**) sulfanilamide effects an arrest of trachoma in about three weeks. Thereafter the improvement is said to continue without further medication. Based on their methods of administration and dosage, the drug was tried on 25 white patients of the Southern Illinois Trachoma Clinics. These patients were selected because they showed signs of "active" trachoma.

Each patient received one-third grain of sulfanilamide a day per pound body weight for a period of one week. In the second week the dose was reduced to one-quarter grain a day per pound body weight. Patients who showed objective or marked subjective symptoms due to toxicity of the drug received a reduced dose, or the medication was interrupted for two to four days.

In order to give a clear picture of the result of the treatment during two weeks' medication and observation, it is necessary to divide the cases into four groups. In the first group were children between 5 and 14 years of age who had no, or only very slight, subjective symptoms and normal vision. Their conjunctiva showed no signs of acute inflammation, but there was dense folliculosis in the fornices. These follicles were distinct, rather prominent, and of equal size. The conjunctiva, especially over the tarsal plate of the upper lid, was not injected and did not show secretion. The pannus in this

group was just developing, or its existence was questionable. These cases, border line cases of follicular catarrh, did *not* show definite improvement after two weeks.

In the second group there were 11 patients classified as "trachoma stage 2-A with succulence." These patients complained of slight photophobia, epiphora, various degrees of blepharospasm, and diminution of vision. Objectively, a velvety conjunctiva with imbedded small follicles was observed. There were various degrees of succulence. The granules were not so prominent and distinct as in the first group. The appearance of the conjunctiva was somewhat muddy and indistinct. There were 2 to 4 millimeters of active pannus in most cases. Cases belonging to this group showed improvement after treatment with sulfanilamide. The most outstanding subjective symptom was a diminution of the epiphora, which was noticed on the second day after beginning medication. A few days later the blepharospasm and the photophobia improved, and the vision, which was usually reduced, ranging from 20/40 to 20/200, improved about two lines on the Snellen chart. Objectively the conjunctiva looked dryer and paler, and the granules decreased in size. The velvety appearance was diminished on the sixth day. On the seventh day the presence of normal blood vessels was observed on the conjunctiva over the tarsal plate of the upper lid, a region which showed the first and most marked signs of objective improvement. The vessels of the pannus became thinner and less distinct on about the tenth day after the treatment was begun. However, they did not disappear during the course of observation. At the end of two weeks the granules in the conjunctiva were still present, but less distinct, the conjunctiva itself was smoother, the velvety appearance was gone. About

*From the Governor Horner Trachoma Clinics of Southern Illinois, Dr. Harry S. Gradle, Director.

**Richards. Personal communication from the U. S. Indian Service to Dr. H. S. Gradle.

75 percent of the patients of this group felt unquestionable improvement in their eyes. Among them is a patient who suffered from an acute flare-up which started two months previous to the sulfanilamide treatment. Another patient had had photophobia for one year, and was without treatment during that period. He improved rapidly within a few days after sulfanilamide medication.

The third group included patients who had trachoma stage 3 without too malignant sequelae due to the disease. Their conjunctiva showed velvety patches and scarring. There was a slight degree of succulence and considerable pannus. Granules in this group were absent. These patients also showed improvement. Their lids looked paler and smoother after a course of two weeks, and the vision improved, due to a slight clearing of the pannus. In this group the sulfanilamide seemed to moderate the course of the disease, and to bring it closer to stage 4.

In the fourth group were three patients who, for the past years, had had very active and malignant forms of trachoma. They had suffered repeatedly from flare-ups, and had vision of less than 20/200, due to marked scarring of the cornea, active pannus, and blepharospasm. They were also classified as stage 3, but the conjunctiva lacked the velvety patches. Instead it was dark red, hypertrophic, and smooth, and the tarsus was very markedly thickened and deformed, due to scars. The blood vessels of the pannus were very thick, and the whole picture was that of a malignant type of trachoma, even though active granules were not present. These patients showed, aside from a very slight paling, only little response to the drug, and their subjective symptoms, as well as the objective findings, did not clearly change.

Many of the patients complained of headaches, dizziness, vertigo, and nausea

after the first doses of sulfanilamide. In most of them the symptoms disappeared after two days. Two older patients had to be taken off the treatment on the second day on account of nausea and vomiting. Three other patients showed signs of cyanosis on the tenth day of treatment, and their treatment with sulfanilamide was discontinued for the rest of the two weeks' period. In one of these three patients the pulse rate went up to 140, but rapidly returned to normal after discontinuance of the drug and administration of digitalis. Three other patients showed slight signs of dermatitis medicamentosa on the forearms and legs on about the tenth day. The subjective symptom of itching and the objective dermatitis disappeared after a short interruption of the treatment. As trachoma is a disease of the more indigent part of the population, it is our impression that one has to be careful with the administration of sulfanilamide, for the general physical condition of these patients is often poor, due to bad living conditions. Medication without very close supervision is inadvisable.

After two weeks of observation and treatment we have the impression that sulfanilamide has a paling and drying effect on the succulent conjunctiva of trachoma stage 2 and milder cases of stage 3. Further, it seems to aid in the healing of pannus in cases that are not too old and not too malignant. Whether it can completely arrest the disease, and prevent recurrences, is a question for future observation.

OCULAR PEMPHIGUS*

FERDINAND L. P. KOCH, M.D.,
Rochester, Minnesota

Chronic ocular pemphigus is an uncommon disease.¹ It is usually associated with

* From The Mayo Foundation.

lesions elsewhere in the skin and mucous membranes. It may be of toxic origin, since changes of the pemphigus type are occasionally found in certain other toxic dermatoses; Welsh,² however, was able to demonstrate a characteristic streptococcus in the blood and nasopharynxes of seven patients with clinical evidence of the disease.

The formation of blisters or bullae in the conjunctiva is followed by submucous invasion by newly formed connective tissue with subsequent cicatrization. Total ankyloblepharon and obliteration of the cul-de-sacs, together with ultimate corneal involvement, eventuate in the condition known as "essential shrinkage of the conjunctiva." The symptoms are very distressing. Secondary infection of the chronic conjunctivitis produces a mucopurulent infection, although remissions may occur. Discomfort becomes permanent as exposure and dryness supervene, and marked photophobia follows the secondary corneal involvement.

The diagnosis in the early stages depends upon recognition of the characteristic bullae, erythematous scaly patches, and early cicatrization in both the skin and mucous membranes. Tenderness of the mouth and throat often are the first manifestations of the disease for which the patient seeks relief.³ The lesions in the conjunctiva must be differentiated from those of erythema multiforme, dermatitis herpetiformis, and from bullous syphilides.

Caro⁴ has recently reported encouraging results in the treatment of dermatologic pemphigus following the administration of sulfanilamide. However, since adequate methods of treating the condition are at present unknown, the prognosis is always bad and, should the patient survive, eventual blindness will ensue.

REPORT OF A CASE

A white man, an electrician, aged 54 years, of English-Irish-Canadian descent, registered at the clinic on April 25, 1938. He complained of having had difficulty with his eyes for the preceding two years, during which period he had observed a slowly progressive, painless reddening of the sclerae. Bilateral and gradual diminution of vision had existed since December, 1937. Coincident with this there had been a slow thickening of each lower lid, the lids gradually having become adherent to the lower portion of each globe. At this time an attempt had been made to improve the refractive correction but this had been unsuccessful. Local treatment had then been instituted, consisting of palliative collyrium and ointments, but this had resulted in increased smarting and burning and in occasional photophobia. Four subcutaneous injections of a substance (which was probably pituitary extract) had been administered but without effect. An occasional reddened area along the gum line below the lower front teeth had begun to appear toward the latter part of the first year. The patient described this as a "bubbling up" of the tissue. Tenderness of the mouth and cheeks and slight soreness of the throat on swallowing ingested material had manifested themselves at the end of this year. As the patient's teeth had never been in good condition he had requested that they be extracted. An upper plate, fitted about a year prior to his admission, had been worn comfortably. Four months prior to admission the lower teeth had been extracted and, as the gums had continued to remain raw and tender, a plate was not furnished. Cutaneous lesions had never been observed at any time. The patient denied having had venereal disease, and the only factor relevant to his illness was a history of duodenal ulcer.

General examination at the clinic revealed a low-grade, chronic tonsillitis, duodenal ulcer (confirmed by roentgenography), mild hypertrophy of the prostate gland, and small internal and external hemorrhoids. Examination of the mouth revealed an almost continuous, grayish-red, irregular patch along the entire upper surface of the lower alveolar ridge which continued laterally over the postero-inferior aspect of the left cheek. One small, clear, intact bulla was seen on the anterosuperior surface of the alveolar process over the site of the first right incisor tooth. Another characteristic bulla was observed in the upper portion of the right pyriform fossa. No lesions were observed over the hard or soft palate or on the lips or skin. All laboratory tests gave essentially negative results.

Ophthalmologic examination revealed the vision in the right eye to be 6/15, with correction, and in the left eye 6/20, with correction. Near vision had been reduced to the ability to read 14/35 (American Medical Association rating) with each eye, with correction. No improvement was obtained on subsequent refraction tests. The lid of each eye opened and closed normally and the margins approximated well without distortion. The palpebral fissures were equal and normal in appearance. Adequate drainage of tears was accomplished by way of the normal punctum and canaliculus of each upper lid. The skin surface of each lower lid presented a slight, brawny induration which was most marked at the margin; the cilia, however, were normally placed. The lower conjunctival fornix of each eye was approximately equally foreshortened to only a third of its normal extent. The partial obliteration by irregular thickening of each cul-de-sac had been accomplished by submucous cicatrization of both the palpebral and bulbar conjunctival sur-

faces. This involved the entire inferior half of each eye and extended from just above the horizontal axis temporally, sweeping across below the cornea to involve almost the entire area exposed by the palpebral fissure over the inner canthus. The erythematous and thickened palpebral and bulbar conjunctiva presented a moderately uneven surface which was studded with irregularly rounded and elongated, slightly elevated, glistening gray patches. Two small, characteristic, red bullae, typical of ocular pemphigus, were observed in the middle third of the right lower lid near the palpebral-ciliary margin. These were 2 mm. in width, 1 mm. in height, and 4 mm. in length, and they ruptured in a few hours. No bullae were ever observed in the left eye. The lower puncta had been involved in the process and, anatomically, no longer existed. Adhesions between the palpebral and bulbar surfaces already had appeared and were more manifest temporally and nasally than centrally; however, those occupying the inner canthal area of each were rather prominent (fig. 1). The external ocular movements were definitely and equally, but only moderately, limited in all the cardinal fields of action except for apparent unimpairment on horizontal and downward convergence.

The remainder of the examination gave essentially negative results. The corneas showed no manifest pathologic changes; the anterior chambers were of normal depth; the tension with the Schiötz tonometer was 11 and 13 mm. of mercury in the right and left eyes, respectively; the irides were normal in appearance and function, the pupillary reactions to the usual stimuli being satisfactorily performed, and the lenses and the vitreous bodies were clear. The ophthalmoscopic findings were essentially negative, as were also the corneal microscopic observations.

Fig. 1 (Koch). Bilateral pemphigus of conjunctiva, showing foreshortening of mucous membrane, partial obliteration of lower cul-de-sacs, and symblepharon of the internal and external canthi.

The rough fields were negative. The laboratory findings were also essentially negative, no parasites, unusual bacteria, nor an eosinophilia having been demonstrated.

Local treatment was instituted immediately following ocular examination on the day of registration. This consisted chiefly of irrigations with 2-percent boric-acid solution followed by 0.5-percent pontocaine drops. Vitamin A (10,000 units per gram) ointment in a light base was placed in both fornices of each eye. This routine was followed daily during the three weeks the patient was under observation. Epithelization of the lesions was characteristic of the moderate improvement observed. The conjunctival surfaces became somewhat smoother, the grayish patches became smaller and fewer in number, and the subjective symptoms of which the patient complained no longer manifested themselves. Distance vision improved with correction in the right eye to 6/12, and in the left eye to 6/15, and it became possible for the patient to read 14/24.5 (American Medical Association rating) with both eyes, with correction.

Upon the use of a mild sodium-borate mouth-wash three times daily the lesions in the mouth followed the same general course as those in the eyes. The bulla in the right pyriform fossa was replaced by a steadily diminishing grayish patch.

The patient was not hospitalized, general treatment consisting solely of the administration of sulfanilamide to the point of tolerance. This was begun on the day of registration. Two tablets of 5 grains (0.3 gm.) each were given orally three times daily for seven days until vague nausea and continued vertex headaches appeared. After this the dosage was reduced by one half for two days, when the original dosage was resumed. The dosage was then increased to a total daily ingestion of 60 grains (3.88 gm.) and this was continued to the day of dismissal three weeks after the patient's appearance for examination. A more intensive course of treatment was not advised because of the doubtful benefit to be derived.^{1, 3} The patient was dismissed for continuation of the treatment at home under the care of his family physician.

SCLEROTOMY SCISSORS FOR ENLARGING CORNEAL INCISIONS*†

CONRAD BERENS, M.D.

New York

These scissors were constructed because of the need of a pair of strong scissors with long curved blades with which to make sections in the corneo-scleral junction. The usual procedure is to make this incision with a Stevens scissors, but this has been found to be awkward.

Fig. 1 (Berens). Sclerotomy scissors for enlarging corneal incisions.

Description. These scissors (fig. 1) have spring shafts, 90 mm. in length, at one end of which are curved blades. At the other end is a screw joining the two ends of the spring. The blades, which are 11 mm. in length, are slightly curved. The upper and lower blades are blunt and the lower blade ends in a probe point.

These scissors are made in two models: one for incisions to the right and one for incisions toward the left. However, one

scissors may suffice by directing the handle downward when cutting to the right and holding the handle upward when cutting to the left.

Use of the scissors. The scissors have been found particularly useful in enlarging cataract sections and for opening iridosclerectomy and iridocorneosclerectomy wounds for glaucoma when the wound has ceased to filter. The scissors are also useful in completing the circumcorneal conjunctival incision in enucleation of the eyeball and in performing other operations on the conjunctiva.

A CHART FOR TESTING VISUAL ACUITY AND ASTIGMATISM*

CONRAD BERENS, M.D.

New York

AND

S. JUDD BEACH, M.D.

Portland, Maine

This test chart is an attempt to combine the several different functions for which such charts are used. It furnishes a test of the visual acuity, adapted to young and old patients, with the different mentalities. It also furnishes a means for estimating the refraction, giving information of more than usual accuracy with regard to the amount and axis of the astigmatism.

* Made by V. Mueller and Company, Chicago, Illinois.

† Aided by a grant from the Ophthalmological Foundation, Inc.

* Aided by a grant from the Ophthalmological Foundation, Inc.

The special features that this chart (fig. 1) possesses are that (1) visual acuity may be accurately tested in children and in illiterate patients by the use of the E test, (2) for other patients and to verify the E test, the international broken ring may be used, (3) the ZN's and crosses** are useful for determining the astigmatism, and (4) usual test letters are also furnished to test both visual acuity and refraction in the conventional way.

The numbers at the side of the chart parallel with each line of figures conserve the examiner's time in designating the line to be read.

A NEW PRISM BAR*†

CONRAD BERENS, M.D.

For several years we have been using racks of glass prisms** numbered from 1^a to 50^a for performing the screen test to measure heterophoria or heterotropia rapidly in prism diopters. They have also been used for giving prism converging, diverging, and supraverging exercises. Although these racks save much time they have a number of disadvantages. The cost is prohibitive and the prisms are easily chipped and scratched. Furthermore, the glass prism racks are heavy and cumbersome to use. Therefore, for the past few years we have experimented with various

Fig. 1 (Berens). Prism rod with 100^d prism at the thick end.

Fig. 2 (Berens). A new prism bar.

substitutes for glass which have similar indices of refraction to glass and have studied the question of molded prism bars made of glass and substitutes for glass. The molds would be unnecessarily expensive and the finished products could not be guaranteed.

Prism bars, made of transparent material and filled with water and other fluids, were constructed but were not satisfactory. Finally a solid substitute for glass was ground and polished into a long rod with a 100^d prism at the thick end (fig. 1). It was a disappointment to find that the vertical prism produced by the diverging sides made the rack inaccurate and practically useless.

The prism bar illustrated in figure 2 was finally constructed. It is 12 inches in length, containing prisms from 1^d to 50^d. At the ends of this bar there are ground extensions which may be used as handles and for performing the screen test.

The bar, which is made of one piece of material with an index of refraction of 1.52, is numbered in prism diopters from 1^d to 50^d on the surface made by the base of the prisms.

Advantages. The advantages claimed for this bar are: (1) it is less expensive than glass prism racks; (2) its lightness makes it much easier to handle, especially in performing the screen test when it is necessary to superimpose square prisms; (3) the material is colorless, difficult to break or chip, and apparently more transparent than glass; (4) if the surface becomes slightly scratched it may be easily repolished; (5) the material used produces a more pleasant sensation than glass or metal when in contact with the skin; (6) this prism bar does not seem to show finger marks so readily as glass and is more easily cleaned than the racks in metal frames.

THE PRODUCTION OF TRANSITORY OPACITIES OF THE LENS IN RODENTS

DR. CAROLINE TUM SUDEN said that in mice, after a single intraperitoneal injection of adrenalin (0.5 mg. to 0.76 mg. per 100 gm. body weight) rapid clouding of the lens occurred in approximately one half of the test animals and disappeared within two to three hours after onset. In rats, which are twice as susceptible to the fatal effects of adrenalin as mice, formation of lens opacities with survival was rare. However, in the latter species, administration of adrenalin (0.3 mg. to 0.5 mg., per 100 gm. body weight), superimposed upon a moderate degree of histamine shock or adrenal insufficiency, produced lens opacities in 57 to 85 percent of the rats, one third of which survived with complete loss of the opacity. Similarly in mice, histamine increased the incidence of opacity formation from 50 to 90 percent and decreased the mortality rate from 15 to 7 percent.

The phenomenon was not correlated with a systemic rise in blood pressure but occurred during the period of marked hyperglycemia following the injection of adrenalin, as Collevati had previously determined in experimental animals.

FACTORS INFLUENCING THE INCIDENCE OF GALACTOSE CATARACT IN RATS

DR. HELEN S. MITCHELL said that the rat has proved to be a suitable animal for use for research on cataract because in this species opacities of the lens may develop as a result of certain nutritional disturbances, while spontaneous cataract is

rare. The discovery that cataract would occur in rats fed on high levels of lactose was made in the Battle Creek laboratory in 1933 and first reported to the American Society of Biological Chemists in the spring of 1934. Control experiments with other carbohydrates, starch, dextrine, maltose, sucrose, and glucose, were entirely negative. Thus galactose, a fraction of the lactose molecule, proved to be the cataract-producing agent in lactose. Dr. Yudkin as well as other workers have repeatedly confirmed these findings.

Galactose cataract resulting from the feeding of either lactose or galactose should be distinguished from vitamin-G-deficiency cataract. Both may be considered nutritional.

A variation in the susceptibility of different strains of rats to galactose cataract and a lesser but significant variation between litters are observations which have proved to be of increasing importance in the study and interpretation of accumulated data.

Studies of the sugar contents of the blood and urine of rats on cataract-producing rations have demonstrated that galactose is the sugar responsible for the high sugar contents of both blood and urine, and that it must be the major etiological factor in this type of cataract.

One dietary factor that seems to alter the rate of development and the incidence of galactose cataract is protein. A low-protein ration (5 percent) appreciably hastens the development of opacities of the lens, and a high-protein ration tends to retard this pathologic change. Other factors, including moderate excess or deficiency of relevant vitamins, have failed to alter the cataract-producing action of galactose.

The earliest lenticular change in rapidly developing cataract is a dense vacuolated film originating at the equator and extending over a large portion of the anterior cortex of the lens, the film later disintegrating as large vacuoles and disappearing before visible opacities develop.

Regression from the stage of complete opacity to that of the nuclear stage has been observed in a large proportion of these experimental animals, but no specific dietary factor nor local medicament has seemed to alter the speed or extent of this regressive change. The age of the animal and the extent of the injury, however, do seem to influence the change.

There is no reason to believe that there is any immediate clinical application or significance in these findings, but the possibility of experimental production of opacities of the lens under carefully controlled conditions permits a new approach to a baffling subject. As a result of these studies numerous problems of a fundamental nature have arisen and warrant further investigation.

DIET AND VITAMINS IN RELATION TO CATARACT

DR. ARTHUR M. YUDKIN said as a result of the knowledge that a cataract is an opaque condition of the lens, many attempts were made to reverse the processes by treating the eye locally and systemically. Because of the poor results following surgical treatment, many of the earlier ophthalmologists were more inclined to treat the condition with nonsurgical methods. With the advent of better surgical technique and local anesthesia, however, the ophthalmologist looked forward to removing the opaque lens by surgical means. Dr. Yudkin believes that every practicing ophthalmologist is satisfied that cataract formation is not due to a single factor but is produced by many conditions. Outstanding among these causes

may be considered a disturbance of the general metabolism of the individual, with a subsequent local change in the eye. Although arteriosclerosis has never been definitely considered as a cause for cataract, it is Dr. Yudkin's belief that it must play a significant role in this respect. In view of the present knowledge of human nutrition it is advisable that all elderly patients having any signs of early changes in the lens be instructed how to live properly. Dr. Yudkin found that by taking a teaspoonful of potent yeast powder twice a day and the juice of at least two lemons daily before meals, tumescence of the lens was decreased and the tissue returned to normal, but when striae were produced by changes in the lens, no improvement was noted. The diminished vision of many of these patients was improved by this therapy, whereas a number remained the same over a period of five years. Dr. Yudkin further believes that we have a right to treat patients with a well-balanced diet supplemented by the vitamins in order to check and prevent this condition.

ATOPIC CATARACTS

DR. WILLIAM P. BEETHAM presented a paper briefly summarizing the relationship of cataract and dermatitis. The data on eight patients with cataracts and atopic dermatitis, hay fever, and asthma were reported, making approximately 40 such cases in the literature to date. Two types of lens changes were observed; one of the usual cataracta complicata type, and one in which a plaque of opacity in the anterior cortex was the dominant feature. A cataract of the latter type was removed intracapsularly and studied histologically. Aqueous was aspirated from two patients and injected intracutaneously with no sensitivity response. The author discussed the role of infection, avitaminosis, endocrine-gland deficiency, autonomic nervous-system disturbances, and allergy. Dr.

Beetham concluded that some unexplained allergic phenomenon was responsible. The term "atopic cataracts" was used to define and classify this association.

PRESENT STATUS OF ORTHOPTIC TRAINING

DR. EDWIN B. DUNPHY said that during the past two years he had tried orthoptic training on 29 patients with concomitant convergent strabismus. Nineteen of these (65 percent) were greatly improved in that their angle of squint was markedly reduced, so that they were able to go without glasses and maintain the visual axes approximately parallel. However, of these 19 patients, only 7 (or 24 percent of the total number) obtained a complete cure in that they had absolute binocular fixation as well as the ability to solve depth-perception charts. At the beginning of the training period all 19 had good binocular vision when slides were presented to them at their angle of squint.

Before training, these 19 cases were all of the accommodative type of strabismus in that the squint was markedly lessened by the wearing of plus lenses, so that in no case was the angle of squint more than 10 arc degrees while glasses were worn. When the glasses were removed, however, the squint increased markedly. After training, the patients were able to remove their glasses without experiencing any return of the squint, and the angle of deviation had been reduced to zero or a negligible amount. The average number of treatments for this group was 29.

Of the 10 failures only three were in cases of the accommodative type, in the

other seven there was a refractive error of less than plus two diopters. In these seven the fusion sense was poor to begin with and never developed to any extent during the period of training. Cases of abnormal correspondence were not selected for training. An average of 13 treatments was given to the members of this group before the case was given up.

Dr. Dunphy said that the question will arise as to how much good orthoptic training really does. We all know of certain patients with squint who, after a period of wearing glasses, become so much better that years later glasses are discarded and there is no return of the squint.

Guibor in 1934 reported a series of 38 cases of internal squint treated by orthoptics. Fusion developed in 99 percent and correction of the squint was obtained in 50 percent. A control series of 40 cases was treated by glasses alone. In this control series fusion developed in 20 percent and complete correction developed in 7 percent. Dr. Dunphy believes this the only controlled series reported in this country, although English and French writers report more or less the same results in their controlled series.

In concluding Dr. Dunphy said that such a small series as his probably would have little value. However, it seems to him that orthoptic training is probably of value in a small group of squint patients who have normal retinal correspondence and well-developed binocular vision when tested on the synoptoscope, and whose angle of squint is not more than 10 degrees when wearing glasses.

Just how orthoptic training works he does not exactly know. It certainly does not create binocular vision when this function is absent. It may, however, improve the patient's appreciation of it so that the desire to use it is stimulated during the exercise period to such an extent that the visual axes tend more toward

parallelism in the effort to maintain it. In other words the duction power is increased.

MERCURY GLOBULE IN ANTERIOR CHAMBER

DR. WILLIAM H. DROEGEMUELLER presented a man, aged 26 years, who had suffered a corneal laceration with iris prolapse of the left eye from the glass of a broken neon sign in October, 1937. When examined, a small metallic globule was noticed in the anterior chamber, which was thought to be mercury: the presence of mercury in the neon tube was confirmed.

Operation consisted of the excision of the prolapsed iris and a sliding conjunctival flap, bridge type. The lens was not injured. An attempt was made to scoop up the globule with a small curette but because of the absence of the anterior chamber and the danger of injury to the lens this was not feasible. The postoperative course was uneventful. A roentgenogram revealed, instead of the single globule of mercury seen at the time of operation, several small particles of radio opaque material below and at the site of the laceration. There were three small metallic globules lying on the zonule of the lens.

For one month following the injury there was a mild inflammatory reaction. Cells persisted in the anterior chamber, and a few large gray-white K.P. The eye cleared, and the corrected vision was

20/20. After the second month, however, attacks of mild inflammation and corneal epithelial edema developed. This was more marked from below. A few deep vessels were noticed in the corneal stroma. The tension remained normal. The patient was treated with sodium thiosulphate intravenously, following the procedure used by dermatologists in the treatment of mercurial irritation from mercurial rubs. Under this management the condition did not progress, although the definite value of the drug may be subject to question. The present corrected vision is 20/30 but it has been as low as 20/70.

RETINITIS PROLIFERANS: A CLINICAL AND
HISTOLOGIC STUDY

DR. BERTHA KLIEN discussed the pathogenesis of two different types of retinitis proliferans. The clinical and histologic characteristics of each type were described and illustrated.

Discussion. Dr. William F. Moncreiff said that the classification of retinitis proliferans into two varieties, from the standpoint of pathogenesis which Dr. Klien proposed, was of basic importance from the anatomic standpoint, and has been correlated by the essayist very strikingly and accurately with the clinical (ophthalmoscopic) findings. This concept has apparently not appeared in the literature. For those whose most immediate interest is in the therapeutic application of clinical and pathologic data, this contribution might also have some significance. While in either type the effort should be to combat the primary disease in advance of the development of retinitis proliferans, or in its earliest stages by way of prophylaxis, one might also be guided in direct therapy of the differing pathogenesis of the two forms of the retinal lesion.

In type 1 the effort should be directed toward promoting the rapid absorption of the exudates or hemorrhages by foreign protein and other intravenous therapy

and by the use of heat, employing especially the newer methods. In type 2, these methods would be expected *a priori* to be relatively ineffective, and the underlying vascular disease must be combated. In most cases the results would be disappointing except in some syphilitic cases and possibly a few diabetic cases. In the treatment of the vascular disease of hypertension, especially, sodium hyposulphate in the form of sulfactol might be found worthy of further trial.

Dr. Robert von der Heydt congratulated Dr. Klien particularly on her artistic and beautiful fundus drawings. He asked about the possible inclusion of congenital cases of massive glial proliferation. These are sometimes hemorrhagic in origin.

Dr. Bertha Klien said the first type is much more apt to lead to retinal detachment than the second, because of the large amount of connective tissue, which has a tendency to shrink with age. The second type, being more vascular, does not shrink so much, and its origin at the nerve head prevents early traction on the retina.

In answer to Dr. Goldenburg, she said that this subject had not been investigated from the hematologic point of view. Possibly alteration of the blood itself, as in polycythemia vera, which occasionally is known to cause an occlusion of the central retinal vein or its branches, might lead to vascular anastomosis and thus to the second type of retinitis proliferans.

HEADACHES OF OCULAR ORIGIN

DR. A. D. RUEDEMANN of Cleveland gave a talk on this subject.

Discussion. Dr. A. D. Prangen said it is important to see that the patient has a thorough physical, and possibly a neurological, examination in a search for all the possible factors which might be causing the headaches. In cases of chronic headache of doubtful origin it seems best that some one consultant be made a sort of clearing house for all the clinical data and that he make an attempt to put the various component parts of the clinical picture together in an attempt to establish a diagnosis.

Dr. A. D. Ruedemann in answering Dr. Fink regarding children and their headaches said the child himself must be considered. He may belong to a social group in which headaches are common or he may come from more or less inferior stock. Such a child comes in contact with normal individuals and is expected by his parents to carry on as a normal child. We must remember that headache is foreign to the child as he starts out in life and someone must impart to him the idea of headache.

DR. ALEXANDER G. FEWELL, *chairman*
THE USE OF PAREDRIE IN CYCLOPLEGIA

DR. I. S. TASSMAN read a paper on this subject which was published in this Journal (August, 1938).

Discussion. Dr. Sidney L. Olsho said that in his office homatropine-refraction cases he has heretofore employed ten instillations at ten-minute intervals. The frequency was to make certain of a thoroughly reliable cycloplegic effect. As recommended by Beach, he had, during the past several weeks, instilled one drop in

each eye at five-minute intervals of the following: 5-percent homatropine solution, 1-percent benzedrine solution, 5-percent homatropine solution. He then waits one hour for the cycloplegic effect. To avoid having the drop squeezed out he has the patient look down, the upper lid is held up and the drop is allowed to flow over the eyeball from an insensitive point well above the cornea. Before it can be squeezed out it has mixed with the tears. The second drop of homatropine might have been omitted, but he was not making an experimental study and was employing the method for effect.

In most instances patients were able to use the eyes for close work on the following day. Postmydriatic examinations are in his opinion advisable.

The cycloplegic effect seemed to him perfectly satisfactory in the new cases. The postmydriatic reduction from the total hyperopia corresponded to that made after thorough homatropinization. In those which were reexamination cases, the mydriatic and postmydriatic results seemed also to correspond to his expectations following the homatropine method.

VERTICAL-PRISM VALUES IN COMMONLY USED BIFOCALS

DR. SIDNEY L. OLSHO said bifocal additions or "adds" are convex and spherical. The intended add is always generated in the form of a circle. In grinding standard adds the optical centers are not established in the centers of the segments but in the centers of the circles of origin. When the add becomes a bifocal-component, only a part or a segment of the circle is used.

The accepted theoretical reading point is 4 mm. below the segment's upper margin. By the Prentice rule we can find the separate vertical-prism effect of the segment at the reading point. To obtain this, multiply the diopter power of the add by

the distance in centimeters of the reading point to the center of the circle of origin. The product equals in prism diopters the vertical-prism effect of the segment at the reading point.

Closely allied bifocals have been given diverse names for commercial motives and also to distinguish high grades from inferior qualities.

Certain bifocals are advertised directly to the wearer, who is obviously not qualified to select the most suitable type.

A meticulous correction of the distance vision, with careful attention to small cylinders and their axes, the certainty that all of the manifest hyperopia is corrected and that a myopia is not over-corrected effect the following advantages: they make a less high addition adequate, therefore less difference between the distance and the near corrections and hence less accommodative and adjustive change for the eyes. In any bifocal the lower the power of the add the less there is of chromatic and marginal aberration.

All modern bifocals are composite lenses. The segment is not an independent unit. The upper or main lens serves as a carrier of the segment. An infracentral, therefore, an excentric area of the main lens becomes an integral part of the composite reading portion. Accordingly the main lens introduces an inescapable prismatic effect in the reading part. If the eye be directed several millimeters below the optical center of a lens of convex power to an infracentral point, which we will call the reading point, it encounters a prism base up. At the reading point of a concave lens the prism is base down.

For practical purposes of the prescriber it will suffice to study the excentric prismatic values in prism diopters downward along the 90-degree meridian. Values so obtained are not precise for points somewhat lateral to this principal meridian.

The prism values are obtained by ap-

plication of the Prentice principle after the vertical effective powers of the lenses have been determined. Spherical lenses are vertically effective 100 percent; cylinder lenses at axis 180° are vertically effective 100 percent; cylinder lenses at axis 90° are vertically effective nil; cylinder lenses at axis 45° and 135° are vertically effective 50 percent. Compute the net vertical effective power of the cylinder and add all of the sphere for total effective power.

To obtain the vertical prism diopters, base up, for plus, or base down, for minus, unavoidably introduced by each of the distance corrections at each of the theoretical reading points (.8 cm. down from optical centers), multiply the total vertical effective power, plus or minus, of each distance correction by .8.

Dropping below the optical centers of distance corrections of unequal vertical effective powers, the eyes encounter progressively increasing vertical-prism disparity.

To ascertain the vertical-prism imbalance at the theoretical reading points, carefully compare the right and left products.

Trouble involving costs, discomfort, and reproach may be forestalled if the prescriber of bifocals will ask himself; (1) in bifocals made on this prescription will there be, within the natural reading zones, two corresponding points at which the vertical-prism imbalance will be less than one prism diopter? If so, they may be tolerated. (2) Will the vertical-prism imbalance at two natural reading points exceed two prism diopters? If so, prolonged fusion at the near point will be very difficult, if it be possible.

Standard segments of equal powers and size do not alter a disparity. Uncorrected vertical-prism imbalance may be sufficient to make bifocals unwearable. If a hyperphoria be present, a vertical-prism imbalance in the lenses establishes in the

reading zone a dominance either of the appropriate or of an adverse prism effect. This must be foreseen by the refractonist.

A hyperphoria may be too little to require any help when vision is directed through the central or equatorial zones. Analysis may furthermore disclose in the infracentric reading zones of the lenses, a vertical-prism imbalance appropriate for the existent hyperphoria. In this case no vertical prism is prescribed in the upper lenses.

On the other hand, lens analysis may disclose in the reading zones a vertical-prism imbalance incompatible with the existent hyperphoria, the reading-zone prism being base up or base down on the wrong eye. In this case the burden is lightened all around by prescribing in the upper lenses for all of the hyperphoria.

OBLITERATION OF PERICORNEAL BLOOD VESSELS FOR VARIOUS TYPES OF KERATITIS—FURTHER OBSERVATIONS

DR. TRYGVE GUNDERSEN said a carefully selected, but consecutive, series of 35 cases has been studied. These comprise a group of patients with chronic corneal disease which resisted the usual forms of treatment. The types of keratitis were grouped as follows: chronic dendritic keratitis, 6; ocular rosacea, 7; tuberculous keratitis, 12; keratitis from trauma, 2; lipin interstitial keratitis, 2; trachoma, 5; hypopyon ulcer, 1; unclassified, 1.

Obliteration of vessels was usually performed with a sharp needle attached to the diathermy unit. In a few instances, cutting instruments were used.

Some cases have been followed for almost five years. The results obtained have been classified into 4 groups: excellent, 12; good, 9; fair, 9; unimproved, 6.

Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to *Dr. Lawrence T. Post, 640 S. Kingshighway, Saint Louis.*

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver.*

Subscriptions, applications for single copies, notices of change of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 640 S. Kingshighway, Saint Louis.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

NEW DRUGS FOR THE TREATMENT OF GLAUCOMA

It is generally conceded that when well-established simple glaucoma occurs in clinic patients surgery is indicated because of the impracticability of follow-up. Whether this is true in private practice or not is less clear. Certainly there are many cases in which the doctor will choose drug therapy for one reason or another, and even if surgery has been the choice, it is not infrequently necessary to supplement partial success with drugs.

Until a few years ago the only known medication was pilocarpine and eserine, and these are not always satisfactory, being sometimes too irritating and sometimes ineffective. A valuable recent addition to therapy was concentrated adrena-

lin, especially in the form of two-percent suprararenin bitartrate. None of these, however, is perfect; a constant lookout should therefore be maintained for other drugs.

In this issue of the Journal appears a paper on the use of two new therapeutic agents, mecholyl and prostigmine. The former is suggested for acute and congestive types of glaucoma while the latter is advocated for chronic simple glaucoma.

Mecholyl, a form of acetylcholine, is to be used either by instillation or retrobulbar injection. Like all acetylcholine products it acts as a vasodilator of capillaries, and presumably its favorable action on the eye is by elimination of waste or other abnormal products by the increased flow through the enlarged vascular bed. This is supposed to be similar to the

method of action of adrenalin after the primary constriction is over. Mecholyl must—like suprarenin—be administered cautiously; not like adrenalin because of danger both locally and systemically, but only because of the systemic reaction and possible heart stoppage. This is true especially when injected in cases of asthma or bronchial allergy, and the administrator is warned to have atropine always ready for injection should the drug act alarmingly; not exactly a pleasant thought. However, the drug is reported efficacious where other local treatment has failed and is therefore worthy of a trial.

Equally important may be the second drug described; namely, prostigmine. This, according to the author, is more potent than pilocarpine and eserine in chronic simple glaucoma in that it is effectual where these have failed. Furthermore it seems to act well in combination with mecholyl.

The need for additional armamentaria for the control of glaucoma is so urgent that these promising drugs should certainly be given a trial. But even the best drugs provide only symptomatic treatment and the study of the fundamental glaucomatous condition must be continued unremittingly because this disease of middle and late life obviously is becoming more frequent as the life span lengthens.

Lawrence T. Post.

SULFANILAMIDE FOR TRACHOMA

This drug, sometimes called prontosil album, or white prontosil, has come into prominence as a remedy to combat various diseases. Infections due to streptococcus of different varieties, pneumococcus, staphylococcus and gonococcus, are all indications for its use. Reports on its beneficial effects now occupy an impor-

tant place in current medical literature. It seems to have a wide and important antibacterial action within the body. Whether trachoma is caused by bacteria, or whether it is due to a virus, may not be settled; but sulfanilamide has been used for trachoma with rather striking benefit. In our lack of knowledge of the cause and pathology of trachoma, it is worthy of trial.

At the San Francisco meeting of the Section on Ophthalmology of the American Medical Association, some of those present testified to the beneficial influence it seems to exert in trachoma. Favorable reports have been received of its use for trachoma among the Indians in different parts of this country. Since hearing of it, several ophthalmologists have tried the drug on trachoma patients and found it beneficial. Its efficacy has been especially apparent in the checking and clearing up of corneal lesions.

In the *Lancet* for October 29th, Dr. Kirk, of Khartoum, Africa, and two colleagues give their experience with sulfanilamide in 25 cases of trachoma among the natives of Central Africa. In all the cases but one there was improvement of the eye conditions. In three cases with less than one month of previous treatment there was rapid improvement in two and slower improvement in the third. Among eight cases that had previously been under treatment "for months," six showed rapid improvement, one slow improvement, and one improved at first and then suffered a relapse. Four cases that gave history of previous treatment for years, and eight that gave no history of previous treatment, all improved under sulfanilamide. Where trachoma was complicated with vernal conjunctivitis (spring catarrh), the results were not so good.

The drug was given in tablets, one-half gram each, three times a day for seven days; and then an intermission of seven

days. In one case there was no intermission, and it improved rapidly. Sulfanilamide, like other new drugs of known power, must be used with caution. Great value in combating the disease for which it is used may be offset by danger of very undesirable or even fatal effects. This has been illustrated by the danger of dinitrophenol causing cataract. Intermissions in treatment have been used to guard against possible dangers of sulfanilamide. It belongs to a class of drugs that sometimes damage the blood-making organs, and cause death by leucopenia (agranulocytosis). This is sometimes, perhaps, caused by the original disease, but sometimes probably from the effect of the drug. If used long, blood counts should be made from time to time; and if the leucocytes fall below the normal number, the drug must be stopped.

It now seems we may have in sulfanilamide a drug that may cure a disease that has been known for thousands of years as a most important cause of blindness. It should be tried, with proper precautions, in every case of trachoma that is surely recognized and that may be properly watched and controlled. Can it cure? Is the cure permanent? How is the drug best used? What must be done to guard against its dangers? A large number of eye physicians and general practitioners may be properly expected to seek the answers for these questions.

Edward Jackson.

HYPERTENSIVE RETINITIS

Much of the language of ophthalmology dates back to remote antiquity. The name "cataract" was given to something which was assumed to fall across the sight. "Glaucoma" was the term applied to a condition of blindness associated with a green (or blue-gray) shimmer in the pupil. These and other expressions were

of Greek origin, because Greek physicians had laid the foundation for medical knowledge as it was still accepted and applied through the period of the Roman Empire and the centuries of the Renaissance, with its revival of classic learning and its dim groping for new scientific facts.

Our study of the ocular background in the living subject is about three fourths of a century old. Its terminology is partly antiquated and is often confusing. The term "retinitis," implying an inflammation of the retina, is attached to a number of conditions in which the retina is certainly not "inflamed," and in which the changes are of a degenerative character. To the presence of an excess of circulatory fluid in the nerve-head we often apply the peculiarly idiomatic title of "choked disc," and those who prefer a more international terminology substitute for this the term "papilledema," whose Greek origin would seem to imply a watery swelling of a protruding structure, whereas the normal optic disc represents rather a depression than a protrusion as related to the general fundus level.

The exact significance of retinal changes is often veiled in mystery. Particularly is this true as regards the relationship between retinal vascular changes and disturbances of the general vascular system. What essential distinctions are there between diabetic disturbances of the retina and those encountered in association with nephritis? How far can we interpret the grave systemic implications of general vascular hypertension, or of renal degeneration, on the basis of our ophthalmoscopic findings?

It is interesting to recall the origin of the expression "albuminuric retinitis," still more or less generally used for a group of changes of which the most striking feature is a star-shaped pattern in the macular region. Before the invention of

the ophthalmoscope, it had been common knowledge that loss of vision often occurred in association with dropsy. When the local basis for such loss of vision was found in the retina, the "retinitis" was called "albuminuric" because albuminuria was one of the prevailing symptoms of nephritis. We now know that albuminuria has no direct relationship to the retinal changes, and that indeed the latter may exist without the former.

Bright, with whose name the subject of nephritic disease has been so closely associated, assumed a cerebral location for the visual disturbances. Other writers attributed the retinal hemorrhages and other changes to increased pressure from cardiac hypertrophy. But the "retinitis" may occur in the absence of any such cardiac change.

The circulatory theory explained the retinal degeneration as depending upon the vascular changes which are so striking in the microscopic anatomy of severe cases, especially in the form of hyalin degeneration of the walls of the small arteries and the capillaries. Unfortunately for this theory, vascular changes may be entirely lacking in severe recent cases of "albuminuric retinitis."

The mechanical theory held a persistent angiospastic ischemia of the retinal vessels responsible for the conditions found with the ophthalmoscope; explaining the tissue changes as due to disturbance of nutrition by reason of deficient blood supply. Wagener and Keith have attached great importance to hypertension associated with arteriolar sclerosis.

In a monograph on this subject presented by request to the Société d'Ophthalmologie de Paris as its annual "report" (*Bulletin de la Société d'Ophthalmologie de Paris*, 1938, November; 200 pages including bibliography of 19 pages) Dubois-Poulsen takes exception to the title—"hypertensive retinitis"—under

which the subject was referred to him. He points out that in the phenomena under consideration there are neither infectious nor inflammatory lesions. The noun "retinitis" and the adjective "hypertensive" are not, he says, adapted to the sense in which they are used. He agrees with Fishberg and Gresser, who would adopt the term "hypertensive neuroretinopathy." (See Fishberg: "Nephritis and hypertension," Philadelphia, Lea and Febiger; and Gresser, *American Journal of Ophthalmology*, 1935, volume 18, page 426.)

Dubois-Poulsen suggests that greater importance should be given than previously, in the ophthalmoscopic picture of the retinopathies, to papilledema and the sphygmoscopic signs. He insists that there is nothing specific in the character of hypertensive retinopathy, but that it is merely a specialized reaction of the retinal tissue to the underlying systemic pathology. Arterial hypertension is the most frequent factor, manifesting itself in various clinical forms. Renal insufficiency is a factor almost equally important but less frequent, and the renal lesions are of a vascular type. However, arteriosclerosis, spasm, arteriolosclerosis, and local arterial hypertension may all alike exist without any retinopathic manifestation.

Who can say whether the renal lesions are secondary to the arterial hypertension, or the latter to the former? This has been one of the most debated problems in general pathology, and is not yet entirely settled. In the development of retinopathy nephritis may precede or may follow hypertension. But retinopathy may appear in the course of arterial hypertension without discoverable renal lesions, either functional or anatomic. Thus it seems logical to admit that the hypertension dominates the pathogenesis and that the renal factor is of less importance.

Direct proof for either side of the argument is lacking.

The old notion of arteriosclerosis as the underlying vascular factor has been replaced by the newer conception of arteriolar sclerosis. Thus an increased importance is attached to ophthalmoscopic examination of the smaller branches of the retinal arteries, and we are reminded once more that the background of the eye is the only place in the human body where blood vessels of arteriolar caliber may be studied in the living subject. Dubois-Poulsen lays stress upon the fact that the great majority of cases of "retinopathy" are accompanied by hypertension of the cerebrospinal fluid. This hypertension may be so severe as to create a special form simulating cerebral tumor by the presence of such functional signs as headache and vomiting, especially when complicated by papilledema.

The therapeutic possibilities in such cases are not encouraging. Dubois-Poulsen mentions, as offering the greatest prospect of symptomatic improvement, cerebrospinal decompression. Its results are often very incomplete and very inconstant. The procedure is dangerous if the decompression is excessive, and if inadequate attention is paid to the following contraindications: cardiac insufficiency, greatly elevated general arterial pressure, and very violent headaches. If the general blood pressure does not fall after puncture, decompression is useless. It is suggested that trial should be made of adrenalectomy and splanchnotomy. Some encouraging results have followed irradiation of the adrenal region.

BOOK NOTICE

DOCUMENTA OPHTHALMOLOGICA. Edited by A. Juhász-Schäffer. Volume 1. Paperbound, 482 pages. Masson et Cie, Paris, 1938.

The Documenta Press which has been publishing the Documenta Gynaecologica, Documenta Oto-Rhino-Laryngologica, Documenta Dermatologica, Documenta Neurologica, and so on, has now entered the ocular field with the Documenta Ophthalmologica.

The purpose of these Documenta is to present monographs on ocular subjects by outstanding workers in their particular fields. They attempt to condense the extant knowledge to date on the subject and to give their own opinions. Published as an international project with editors in many countries, the first volume contains a variety of material, extremely well handled by eminent ophthalmologists. The list is so excellent that it is worth the space to give it in full: R. Granit, Helsingfors: Processes of adaptation in the vertebrate retina in the light of recent photochemical and electrophysiological research. F. P. Fischer, Utrecht: Der Wasserhaushalt des Auges und seiner Teile. P. Bailliart, Paris: La circulation rétinienne. P. Karrer, Zürich: Die Bedeutung der Carotinoide für die Augen. A. Juhász-Schäffer, Milano: Le Vitamine nei loro rapporti con l'oftalmologia. A. Magitot, Paris: Symptomatologie du Glaucome et le problème pathogénique. J. Nordmann et Reiss, Strasbourg: Le problème physico-chimique de l'opacification du cristallin.

No attempt will be made to epitomize these articles, which are already condensations from a vast literature, one of them having 29 pages of bibliography. How successful the publication will prove in the United States is difficult to estimate because of the inability of the great majority of our ophthalmologists to read foreign languages. Only one of the seven articles is written in English. It is a pity that all of them cannot be translated into English because they are too good to be missed. The journal is worthwhile, and if

the successors to the first volume are as good as it is, there should be a definite place for this publication in the ophthalmological field.

Lawrence T. Post.

CORRESPONDENCE

TRACHOMA BODIES FROM THE NORMAL CONJUNCTIVA

1528 Crescent Street,
Montreal, Canada,
February 1, 1939

Editor, American Journal of
Ophthalmology.

Sir:

In the Ophthalmic Record of June, 1910, the undersigned in a short article reported the finding of trachoma bodies in the normal conjunctiva. At that time, in a general search for trachoma bodies in all sorts of tissue, a number of babies at the Maternity Hospital were examined, and in two of the apparently normal cases, numerous inclusion bodies were found.

Following the War period, resumption of this work was again undertaken, and

since that time have been seen a number of cases with inclusions which would have entirely escaped observation because of the mildness of the clinical signs, except that we had been constantly on the lookout for inclusion cases. This occurred not only in infants but in adults as well.

In the light of these cases, it has been my belief for some time that those previously reported as normal were mild inclusion conjunctivitides. Topley and Wilson in their latest edition state "whatever the structure of inclusion bodies may be, their presence in tissue is a sure sign of infection." With that statement I am in accord in that I now believe that the presence of inclusion bodies in the conjunctival cells, either free or within the cells, is indicative of a pathological condition.

(Signed) S. Hanford McKee, M.D.

ERRATUM

In the abstract of the Auffinger paper on page 102 of the January issue, the word "amber" was by editorial mistake substituted for "meerschau," the correct translation.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is only mentioned in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Wheeler, J. M. Implantation of hollow grooved body into orbit for filling; late after enucleation of eyeball. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 709-712.

Correction of the appearance of sinking of an artificial eye is best accomplished by an implantation into the muscle cone behind the fundus of the socket. For this a special hollow glass body, in which four grooves have been made for reception of the recti muscles, is implanted behind Tenon's capsule. A horizontal incision is made in the conjunctiva completely across the fundus of the socket and then the conjunctiva completely dissected from Tenon's capsule, then a vertical incision is made through Tenon's capsule deep into the orbital tissues and the grooved body inserted. Mattress sutures are placed in Tenon's capsule so as to cause overlapping of the flaps and the conjunctiva is closed with interrupted sutures. A firm pressure dressing should be applied for

about one week. A prothesis may be fitted three weeks after operation. (Discussion.)

CONJUNCTIVA

Agnello, Francesco. Papilloma of the caruncle. *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 553-559.

The writer gives a good description of the anatomy of the lacrimal caruncle and discusses the various tumors which arise from this structure. He cites the case of a 62-year-old man with a papilloma of the left caruncle. From the histologic findings he classifies the growth as a papilloma with cutaneous epithelium. Up to 1928 only 189 tumors of the caruncle had been reported. (2 figures.)

Eugene M. Blake.

Mathis, Giovanni. Ocular lesions in myxomatosis of rabbits. *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 543-552.

Myxoma is a particular affection of rabbits and presents a characteristic and nearly constant pathologic picture, ending in death within a few days. The author studied a series of cases in rabbits and concludes from clinical and

histologic examinations that the myxomatous virus induces severe acute catarrhal conjunctivitis with striking macroscopic and microscopic alterations of the connective tissue of the lids. The changes are similar to those occurring in the subcutaneous tissues of other parts of the body, especially about the natural orifices. (4 figures.)

Eugene M. Blake.

Muscatello, Francesco. A peculiar histologic aspect of bilateral conjunctival hyperplasty in trachoma. *Boll. d'Ocul.*, 1938, v. 17, March, pp. 195-210.

The writer describes the histomorphology and histochemistry of a hyperplastic granulomatous conjunctiva which had been affected by trachoma. The patient was a woman 41 years of age. (Bibliography, 9 figures.)

Melchior Lombardo.

Poleff, L., and Nain, M. The Weill-Félix reaction in trachoma and its theoretical and clinical value. *Revue Internat. du Trachome*, 1938, v. 15, July, p. 113. (See *Amer. Jour. Ophth.*, 1939, v. 22, Feb., p. 217.)

Sobhy Bey. A propos "The pyrexias and trachoma." *Rev. Internat. du Trachome*, 1938, v. 15, July, p. 126.

Monocular trachoma was cured by an attack of measles. This case is cited to show the basis for the author's success with milk injections in trachoma.

J. Wesley McKinney.

Thygeson, P., and Richards, P. Nature of the filtrable agent of trachoma. *Arch. of Ophth.*, 1938, v. 20, Oct. pp. 569-584; also *Trans. Sec. on Ophth.*, *Amer. Med. Assoc.*, 1938, 89th mtg.)

The virus of trachoma, with the

viruses of inclusion blennorrhea and psittacosis, appear to form a group transitional between the rickettsiae and the typical viruses. The results in 22 filtration experiments are summarized to show that the etiologic agent is filtrable under certain conditions. The facts presented by a summary of 320 cases in ten series indicate that this agent has the characteristics of a virus (filtrability, inclusion-body formation, and noncultivability on nonliving mediums), and that it is identical with the elementary body of Halberstädter and Prowazek. J. Hewitt Judd.

Torres Estrada, A. Some rules of conduct for treatment of pterygium. *Anales de la Soc. Mexicana de Oft.*, 1937, v. 11, Jan.-March, pp. 187-204.

Several operative procedures are well illustrated. The author considers it very important in each case to know whether the pterygium has invaded Bowman's membrane. He outlines and illustrates the technique used by himself, the steps of which are briefly as follows: transfixion with a cataract knife, the back of which is then used to separate the head of the pterygium thoroughly from the cornea; resection of the head of the pterygium; removal of the episcleral tissue underlying the body of the pterygium; an incision upward from the upper edge of the pterygium near the semilunar fold, and a second incision downward from the lower edge of the pterygium near the limbus, the flap formed by the upper incision being carried into the gap left by the lower incision so as to form a sutured "N" perpendicular to the palpebral aperture. (The description of this procedure is not entirely clear.) The author regards this technique as less likely than the McReynolds to be followed by recurrence. W. H. Crisp.

6

CORNEA AND SCLERA

Bessey, O. A., and Wolbach, S. B. Vascularization of the cornea of the rat in riboflavin deficiency with a note on corneal vascularization in vitamin-A deficiency. *Jour. Exper. Med.*, 1939, v. 69, Jan. 1, p. 1.

The authors kept albino rats on riboflavin-deficient diets and studied vascularization of the cornea by microscopic, injection, and slitlamp methods. The rats ceased to grow after three weeks, and by the end of the fourth week a marked radial ingrowth of capillaries into the cornea from the limbus vessels could be seen by slitlamp. Later corneal turbidity due to leucocytic infiltration developed. After supplying the deficient riboflavin to the diet, the corneal turbidity usually cleared within 48 hours, and after two weeks the blood vessels could no longer be seen by slitlamp. In reviewing studies on the vascularization of the cornea in vitamin-A deficiency, great similarity between this and the vascularization in riboflavin deficiency was found. The rôle of riboflavin as a respiratory carrier and the altered physiology following keratinizing metaplasia in vitamin-A deficiency suggested that the vascularization in each case might be in response to asphyxia of the corneal stroma. (Illustrations.) George A. Filmer.

Gundersen, Trygve. Results of autotransplantation of cornea into anterior chamber; their significance regarding corneal nutrition. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 645-650.

The finding of the scleral disc in the anterior chamber of a patient on whom a trephining operation had been performed eight years previously suggested these experiments in which the

viability of all corneal layers in the aqueous humor was studied by introducing full thicknesses of cornea into the anterior chamber in seventeen cats and ten rabbits. A disc of cornea was removed from one eye with a mechanical trephine and immediately introduced into the anterior chamber of the opposite eye through a small keratome incision. It was found that the corneal epithelium could not subsist when nourished by the aqueous alone, as it disappeared entirely from each implant. The other corneal tissues can live almost unaltered in aqueous for a period up to the duration of these experiments, twenty months. The endothelium not only lives but proliferates. (Photomicrographs.) J. Hewitt Judd.

Kentgens, S. G. Vitamin-A therapy in corneal lesions. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Oct., p. 1.

The author believes that systemic and local use of vitamin A is useful in herpes, keratitis punctata, marginal ulcers, and catarrhal ulcers. In 48 patients afflicted with one of these lesions and treated with vitamin A, the average healing time was seven days, while 38 patients with similar lesions from whom vitamin-A preparations were withheld had an average healing time of eighteen days. In systemic therapy he uses standardized cod-liver oil; locally, this same preparation as eye drops or made into an ointment.

F. Herbert Haessler.

Kraupa, Ernst. Punctate and annular corneal degeneration. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Oct., p. 34.

In each of two patients, aged 50 and 69 years respectively, a white corneal opacity was observed less than 0.25

mm. in diameter. Slitlamp observation showed the defect to consist of finest bluish-white punctate opacities in several of the more superficial strata of the substantia propria. The entire opacity was surrounded by a ring just under Bowman's membrane, beyond which were a few scattered puncta. There was no corneal vascularization. The manifestations did not change with treatment and diet as do the corneal opacities associated with synchysis scintillans. The annular part of the opacity is unique. It is entirely different from the inflammatory halo surrounding foreign bodies, ulcers, herpes, hemosiderin, the annular rents of Bowman's membrane in keratoconus after blunt trauma, the Kayser-Fleischer ring, or outer or inner embryotoxon or gerontoxon. The ring in question is not sharply delimited and is not closed. The significance of the case is not clear.

F. Herbert Haessler.

Roy, J. N. Tattooing of the cornea. *Ann. d'Ocul.*, 1938, v. 175, Nov., pp. 836-841.

Report of a case of successful India-ink tattooing of a corneal leucoma in several stages. John M. McLean.

Salzmann, Maximilian. Glaucomatous degeneration of the cornea. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 413-464. (See Section 8, Glaucoma and ocular tension.)

Seech, S. G., and Cooper, W. L. Experimental iontophoresis of rabbits' corneas. Report of two cases of corneal dystrophy with treatment by ionic medication. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 624-640.

The literature is reviewed and the results of animal experimentations for the purpose of investigating the efficacy

of zinc sulphate, zinc chloride, barium chloride, sodium chloride, colloidal sulphur, and quinine bisulphate are reported. A definite sequence of tissue changes in the rabbit corneas was found. These changes are divided into reparative or therapeutic, borderline changes, and pathologic or destructive changes. The authors believe that the reparative or therapeutic changes produced by this method of treatment are definitely beneficial, and they report two cases with corneal dystrophy in which the treatment was successful. The tissue changes are shown by photomicrographs. J. Hewitt Judd.

Swindle, P. F. Events of vascularization and devascularization seen in corneas. *Arch. of Ophth.*, 1938, v 20, Dec., pp. 974-995.

The metamorphosis of the arterio-venous anastomoses in the cornea of the Rocky-Mountain bighorn lamb, which is the only animal in which the apparently normal cornea becomes extensively invaded by blood vessels, is not completed until the lumen of the principal arterial trunk becomes spontaneously obliterated. The bouquets of vascular loops vanish rapidly after the lumens of the principal arterial trunks become obliterated. By means of rhythmic injection of India ink or red mercuric sulphide the vascularization of the corneae of various normal and ailing animals has been studied and the results are reported here. An inflamed cornea may become almost completely vascularized by preëxisting scleral and conjunctival vessels before a new blood vessel develops in it. In fact, many vessels may become destroyed in the process. This is vascularization unaccompanied by neovasculogenesis. The development of loops and incomplete loops or diverticula and the spontane-

ous destruction of corneal vessels are described. (Photomicrographs.)

J. Hewitt Judd.

Trematore, M. Parenchymatous keratitis in acquired syphilis. *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 520-534.

Trematore reports a case of interstitial keratitis occurring less than two months after an initial genital sore in a sixteen-year-old boy in whom no signs of hereditary lues could be found. There was no evidence of the disease in the parents or any of the other six children. Wassermann reactions were negative and remained so even after provocative injections. After five months of treatment, the cornea of one eye cleared, leaving no trace of cicatrization or vascularization. The author reviews the literature pertaining to the subject. He cites the rather widely divergent findings as to frequency of interstitial keratitis in acquired syphilis, and discusses the questions of reinfection and superinfection in syphilis.

Eugene M. Blake.

Verhoeff, F. H., and King, M. J. Scleromalacia perforans. *Arch. of Ophth.*, 1938, v. 20, Dec., pp. 1013-1035. Also *Trans. Sec. on Ophth.*, Amer. Med. Assoc., 1938, 89th mtg.

Fourteen cases of scleromalacia perforans described in the literature are reviewed and a new typical case is reported. It is the first in which an eye affected with this disease has been obtained for microscopic examination. The patient was afflicted with rheumatoid arthritis. The primary ocular lesion consists of a sharply defined area of necrotic scleral tissue, which becomes surrounded by a wall of endothelioid cells and is slowly infiltrated with pus cells. This produces a seques-

trum which becomes completely disintegrated and densely infiltrated with necrotic pus cells. The abscesses perforate the sclera and discharge their contents externally, producing the characteristic cavities. Histologically, in their initial stages the scleral nodules are essentially similar to the subcutaneous nodules of rheumatoid arthritis. To avoid intraocular complications from the toxins, curettage of the scleral nodules is suggested. (Photograph, color plate, photomicrographs, discussion.) J. Hewitt Judd.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Ascher, K. Epithelial downgrowth into anterior chamber; regressive changes and healing after roentgen therapy. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Oct., p. 29.

Downgrowth of epithelium into the anterior chamber probably occurs from delayed closure of the wound. It is unlikely that implantation of epithelium into the anterior chamber during operation is a factor. Thermocautery, radium, and roentgen rays have been used therapeutically, not always with success.

In one patient, the author applied roentgen therapy—a total of 1800 r. in five doses at intervals of four to seven days. After the second treatment, the membrane became thinner and gradually disintegrated. The eyeball became and remained normal, with a vision of 6/6. F. Herbert Haessler.

Bencini, Alberto. Congenital familial diffuse atrophy of the choroid. *Boll. d'Ocul.*, 1938, v. 17, April, pp. 217-254.

Two brothers aged 35 and 38 years respectively complained of progressive diminution of visual power and of hemeralopia. Both were myopic. The

fundus examination showed pinkish discs with blurred margins and contracted arteries, a circumpapillary zone of choroidal atrophy diffusely pigmented, and around this a sector of atrophic choroid. At the periphery the fundus had a blackish-red aspect. The pigment, diffusely distributed throughout the fundus, was irregularly massed in some places and absent in others, but nowhere had an osteoblastic form. The visual fields were markedly contracted, and the light sense markedly lowered. The family history is given, and shows only the males affected. In spite of possessing some characteristics in common with pigmentary degeneration of the retina, the present case differed from that entity in the absence of a diencephalic symptomatology, in the possession of normal renal function, and in other ways. (Bibliography, 9 figures, 2 tables, 4 colored pictures.)

Berens, C., Angevine, D. M., Guy, L., and Rothbard, S. Eye lesions in experimental infections, special reference to arthritis. *Amer. Jour. Ophth.*, 1938, v. 21, Dec., pp. 1315-1327.

Friedenwald, J. S., and Stiehler, R. D. Circulation of the aqueous. 7. A mechanism of secretion of the intraocular fluid. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 761-786.

To facilitate continuity of the argument and to avoid confusion, this report on the character and mechanism of the irreciprocal permeability of the ciliary body presents the details of the experimental technique and protocols in small type and the text in large type, but the two portions are so arranged that they may be read continuously. The experiments include investigations of the permeability of the ciliary body to various

acid and basic dyes, the oxidation-reduction potentials of the ciliary body, the enzyme systems of the stroma and epithelium, the stroma-epithelium barrier, the transfer of water and the other components of the blood-aqueous barrier, the capillary wall, and the epithelial-cell membrane. It was discovered that the ciliary body showed an irreciprocal permeability to certain dye stuffs as well as to water, and the behavior of the dyes indicated that an electrical phenomenon was involved. Water and basic dyes are transferred from the stroma to the epithelium, that is, from the blood to the aqueous, and the acid dyes in the reverse direction. An electrical current which transfers the water and cations from the stroma to the epithelium and the anions from the epithelium to the stroma is supplied by the differences between the oxidative and the reductive processes in epithelium and stroma. The electric circuit is completed by an electron transfer through the stroma-epithelium barrier, presumably through the reversible oxidation-reduction system of the barrier. An appendix to the paper contains information regarding identification of the dyes, association or polymerization, and the ionic charge and relative mobility of the dyes.

J. Hewitt Judd.

Robertson, J. D. Some observations on fluid interchange and its bearing on certain ophthalmological problems. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 75.

Combined study of fluid interchange and intraocular pressure confirms the opinion held by the author for the last few years that the aqueous humor cannot be regarded as a dialysate. The response of intraocular pressure to intra-

venous injection of solutions of various concentrations cannot be explained by the simple laws which govern a dialysate. This, combined with other evidence, points to formation of the aqueous humor by the mechanism of secretion.

Beulah Cushman.

Samuels, Bernard. Panophthalmitis and sympathetic ophthalmia. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 804-811; also *Trans. Amer. Ophth. Soc.*, 1938, v. 36.

This discussion includes an explanation of varying amounts of uvea remaining in phthisic globes following closed and open panophthalmitis, the incidence of panophthalmitis in sympathetic ophthalmia, the diagnosis of sympathetic tissue in panophthalmitis, the clinical importance of diagnosis of sympathetic ophthalmitis from the microscopic picture, the ordinary lymphocytic infiltration and sympathetic lymphocytic infiltration in the choroid, and the bearing that the facts presented may have on experimental work in sympathetic ophthalmia.

J. Hewitt Judd.

Valle, Sergio. Concerning Hoffmann's "early leprous choroiditis." *Arquivos Brasileiros de Oft.*, 1938, v. 1, Aug., pp. 31-51.

The author confirms the opinions expressed by Adjemian about forty years ago, namely that the diagnosis of this condition has not been firmly established, and that for its proof all other causes must be excluded.

GLAUCOMA AND OCULAR TENSION

Bellows, J., Punttenney, I., and Cowen, J. Use of sorbitol in glaucoma. *Arch. of Ophth.*, 1938, v. 20, Dec., pp. 1036-1043.

Laboratory experiments on dogs showed that sorbitol was slightly diffusible into the anterior chamber, and the drug was found to be an effective agent in reducing abnormally high intraocular tension when injected intravenously into human beings. The results in twelve cases are tabulated. Because of its slight diffusibility, a secondary rise in tension above the initial value was not observed. It is suggested that 100 c.c. of a 50-percent solution of sorbitol be administered intravenously and repeated in 24 hours if necessary. It is especially useful in those cases not responding to miotics and as a preparation for operation. J. Hewitt Judd.

Bhaduri, B. N., and Biswas, C. K. Effect of dark adaptation on the tension of eyes in patients suffering from epidemic dropsy. *Calcutta Med. Jour.*, 1938, v. 34, Sept., p. 206. (See *Amer. Jour. Ophth.*, 1938, v. 21, May, p. 571.)

Bhaduri, B. N. Enormous reduction of intraocular tension in the unoperated eye following sclerocorneal trephining in the other eye in a case of epidemic dropsy. *Calcutta Med. Jour.*, 1938, v. 34, Dec., p. 532.

A case report of a sixteen-year-old girl with high intraocular tension and vision reduced to light perception in both eyes. Following Elliot trephining of one eye, the tension in the unoperated eye dropped to 37 mm. Hg (Schiötz) and vision shortly returned to normal. Tension in the unoperated eye remained somewhat elevated and

the visual field became further contracted, so trephining was later necessary on this eye also.

Ernsting, H. C. Intraocular tension in electropyrrexia. *Amer. Jour. Ophth.*, 1939, v. 22, Jan., pp. 54-56.

Holmes, W. J. Congenital buphthalmos complicated by dislocation of lens and hemorrhage into vitreous, with complete recovery of central vision. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 757-760.

A man aged 31 years was struck by a finger in his only eye, which was buphthalmic, and on which a Lagrange operation had been performed fifteen years previously. A massive hemorrhage into the anterior chamber and vitreous obscured for a time the fact that the lens was dislocated backward. Later the lens appeared as a freely swinging white mass back of the ciliary region. The author feels that the remarkable final vision, the maintenance of normal intraocular tension, and the absence of any further constriction of the field over a period of a year after the injury are due largely to the fact that the drainage operation had been done early and properly.

J. Hewitt Judd.

Salzmann, Maximilian. Glaucomatous degeneration of the cornea. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 413-464.

Degenerative changes in the cornea occurring in glaucoma may be divided into those of the epithelium, those of the superficial nerves, and pannus extending from the limbus. These are described and illustrated under epithelial opacities, shrinking, swelling, necrosis of the epithelial cells, the for-

mation of superficial vacuoles and hollow spaces in the epithelium, hydropic degeneration of the cells, and the formation of fluid between the epithelial cells. Changes of the superficial nerves include dilatation of the nerve canals in Bowman's membrane, proliferation of the cells of the nerve-fiber sheath, groups of cell nuclei in phlyctenule-like formations in the break in Bowman's membrane, and formation, over the breaks, of islands of avascular connective tissue. The author thinks the entire process could be designated superficial neurodystrophy of the cornea. Glaucomatous pannus always contains blood vessels and proceeds from the limbus between the epithelium and Bowman's membrane. Pannus is less frequent than neurodystrophy, and remains confined to the marginal zone of the cornea.

Under intense varieties of corneal degeneration, there is described an increase in the number of layers of the epithelium with or without elevation in the form of a bulla and a membranous formation within the epithelium.

H. D. Lamb.

Schmelzer, Hans. Observations in the constitutional causes of glaucoma. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 465-479.

Comparison of the blood chemistry in 55 cases of primary glaucoma as compared with that in 45 individuals of the same ages without glaucoma revealed that the cholesterine content was very much increased and the xanthoprotein reaction was positive in almost all the persons with glaucoma. It could be concluded therefore that a certain disturbance of the action of the liver was present in the cases of glaucoma. In addition to local therapy in the

treatment of glaucoma, the author advises accordingly a diet low in fats and high in carbohydrates (much vegetable, salad, fruit, coarse bread, and fruit juices).

CRYSTALLINE LENS

Case, P. H. An interne's experiences with the Verhoeff method of cataract extraction. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 651-656.

The technique of the Verhoeff method is described and the advantages of the corneoscleroconjunctival suture presented. In the author's first series of 57 attempted intracapsular extractions, 51 lenses were removed in capsule. Loss of vitreous occurred in three of the cases in which the capsule was removed intact and in two of the six cases in which the capsule ruptured. The apparent causes of the rupture of the capsule were: poor coöperation of the patient, posterior synechiae which were not freed first, patient's youth, intumescent cataract, and high myopia. A brief report is given of the cases in which the capsule ruptured. J. Hewitt Judd.

Chandler, P. A. Inferior iridotomy in operations for cataract on eyes with posterior synechiae or pupillary membrane. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 641-644; also *Trans. Amer. Ophth. Soc.*, 1938, v. 36.

In order to insure a permanent pupillary opening in those eyes previously affected with iritis or cyclitis, or operated upon for glaucoma, an inferior iridotomy is recommended before the lens is removed. After the usual incision, any posterior synechiae are freed with a spatula, and the iris is split from the lower pupillary margin nearly down to the root with a Noyes scissors. This procedure has given adequate and permanent results in all but one of approximately twenty eyes. Even if the pupil closes no harm has been done. Two illustrative cases are reported in detail.

J. Hewitt Judd.

Ciotola, Guido. Two cases of double-rosette cataract. *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 504-520. (See Section 16, Injuries.)

Cullom, M. M. A new capsule grasping forceps. *Arch. of Ophth.*, 1938, v. 20, Oct., p. 1045.

This is a double-headed forceps designed to grasp the capsule at two points. There is a spread of 4 mm. between each pair of blades. The forceps are shown open and closed in photographs. (Note by editor: The second illustration seems to give a false idea of the relative position of the two pairs of blades.)

Krause, A. C. Chemical pathogenesis of cataract. *Amer. Jour. Ophth.*, 1938, v. 21, Dec., pp. 1343-1355.

Legrand, J. Surgical treatment of dislocated lens in the vitreous. *Arch. d'Ophth. etc.*, 1938, v. 2, Oct., p. 924.

Surgery of the luxated or subluxated lens has always been considered a serious and hazardous operation. The literature is most pessimistic, though many methods have been described, from the

vectis or curette operation of Snellen and Pagenstecher to the transforming of a posterior luxation into an anterior one by pressure from behind, or using mydriasis and then placing the patient in a ventral position. There are practical objections to each of these methods, chief of which is the chance of glaucoma. That is why the author utilizes a small knife with interchangeable blades, constructed by Moria, for transfixion of the lens in the anterior chamber. As soon as this is accomplished the patient is turned on his back, and removal of the lens proceeds in the usual way. Two cases of luxated lens in which the instrument was successfully used are described.

Derrick Vail.

Olmos, E. S. Combined cataract operation. *Anales Soc. Mexicana de Oft.* etc., 1938, v. 12, Jan.-July, pp. 141-150.

The author's technique includes substitution of the Desmarres elevator for the lid speculum, a Kalt suture toward the nasal side, and a conjunctival flap toward the temporal side. (Discussion.)

W. H. Crisp.

Parker, F. C. A cataract operation to reduce the incidence of prolapse of the iris. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 597-603.

The author objects to the usual manner of making the incision on the ground that it stretches the lower portion of the cornea and causes a greater tendency to prolapse of the iris. He suggests fixation above and an incision in which the heel of the knife is raised first, so that the tissues tend to be pushed inward. The next step is to raise the point end of the knife as it is being withdrawn. These motions are repeated until the incision is complete. The

points presented are shown by drawings.
J. Hewitt Judd.

Samuels, Bernard. Pathology of complicated cataract. *Southern Med. Jour.*, 1939, v. 32, Jan., p. 70.

The author discusses lens opacities occurring as a result of other lesions within the eyeball, such as inflammation, glaucoma, tumors, necrosis of surrounding tissues, and mechanical causes. He advises that a good general rule in the treatment of such cataracts is to wait at least one year after the eye becomes free of every sign of inflammation before operating, and then to use the extracapsular method following a preliminary iridectomy.

George A. Filmer.

Tupinamba, J., and Souza Dias, João de. Marfan's syndrome with ectopia lentis. *Rev. de Oft. de São Paulo*, 1938, 6th yr., April-June, pp. 61-66.

Beside subluxation of both lenses upward and to the right, the patient, a girl of eleven years, presented long slender build, muscular atrophy, dry and furrowed skin, and the long bones unduly long and slender. This combination the authors interpret as an abortive form of Marfan's syndrome. But the blood Wassermann was negative.

W. H. Crisp.

Wiederkehr, Willy. Further contribution to senile exfoliation of the anterior capsule, based on slitlamp and histologic findings in 18 eyes from 14 patients between 60 and 104 years of age. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 541-552.

The author confirms the three principal types of senile exfoliation of the anterior capsule as described by Vogt: lamina-like loosening of the superficial

lamella, exfoliation with focal thinning of the capsule, and light flaky-like dissociation of the lamellae of the capsule. This senile exfoliation affects only the anterior capsule and predominantly the thick part near the anterior pole of the lens.

Kalt, E., and Bailliart, P. **A case of juvenile degeneration of the macula.** Bull. Soc. d'Ophth. de Paris, 1937, May, p. 309.

Careful description of the progress of a case in a male aged 34 years. The author discusses the etiology and regards the malady as a vascular insufficiency usually organic, but which may be functional. Harmon Brunner.

Keyes, J. E. L., and Goldblatt, H. **Experimental hypertension. 8. Vascular changes in the eyes.** Arch. of Ophth., 1938, v. 20, Nov., pp. 812-828. Trans. Sec. on Ophth., Amer. Med. Assoc., 1938, 89th mtg.

The eyes of dogs and monkeys with persistent hypertension following constriction of the main renal arteries have been observed for more than five years. The changes described, and illustrated by photomicrographs, are similar to those seen in man with benign and malignant essential hypertension. (Color plate of fundus changes, discussion.) J. Hewitt Judd.

McDonald, R., and Lippincott, S. W. **Angiomatosis retinae.** Arch. of Ophth., 1938, v. 20, Dec., pp. 958-965.

This condition was found in a boy aged fifteen years, in whom the disease had been present since the age of five years. The diagnosis was made in the left eye by ophthalmoscopic examination, and was confirmed by histologic examination of the blind right eye. The authors feel that the initial event is the formation of angioblastic derivatives, represented by cystic dilatations and capillaries, and that the gliosis is secondary. Secondary changes include

exudation, hemorrhages, detachment of the retina, iridocyclitis, secondary glaucoma, cataract, and finally hypotension with phthisic changes. The tumor is shown to be of vascular origin, representing a congenital malformation, even though the gliosis is so marked that it nearly masks the true derivation of the tumor. (Photomicrographs.)

J. Hewitt Judd.

Magitot, A. **Recent and partial idiopathic detachment of the retina.** Ann. d'Ocul., 1938, v. 175, Nov., pp. 797-807.

A 35-year-old non-myopic patient had a detachment of the temporal side of the retina without associated trauma. Twenty days after it was discovered the eye was enucleated, and it was studied in serial sections. No tumor was found. There was a small disinsertion at the ora. There were no traction bands or abnormal proliferations in the vitreous.

On the attached as well as the detached side the pigment-epithelial cells showed hyaline production, pigment rarification, and alteration in form. Under the retina which had not become separated, an albuminous fluid was beginning to infiltrate between the choroid and the epithelial layer. All the pigment epithelium in this eye, including that of the iris, seemed to be undergoing pathologic changes. In the adherent side the retina itself appeared quite normal and showed none of the degenerative changes of the detached areas. The choroid was not hyperemic, sclerotic, or inflamed. The choriocapillaris, alone, showed small atrophic areas.

The author suggests that primary lesions of the pigment epithelium cause formation both of hyaline excrescences and albuminous subretinal fluid, and that a poorly understood disease of the

pigment epithelium may be the underlying factor in "idiopathic" detachment.

John M. McLean.

Matsuda, S. The injurious action of hepatic and splenic toxins on the eye. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 503-512.

Experiments with rabbits showed that toxins from the spleen exerted an injurious action upon the eye similar to that of hepatic toxins. This fact disproves a specific relation between the retina and the kidneys, and involves the conclusion that nephrotoxic material in man plays an essential factor in the production of albuminuric retinitis.

H. D. Lamb.

Measurement of the average width of retinal vessels and its meaning in differential diagnosis of hypertension and nephritis. *Schweiz. med. Woch.*, 1938, Oct. 29, p. 1215.

The non-indicated author of this review states that according to the latest advances in the study of hypertension and nephritis, observations on the width of the arterioles are most essential. A new and accurate method to measure this has been found by Lobeck of Jena. Further, he states, the method is very quick and simple. Lobeck has had Zeiss make a measuring ocular which is attached to the Gullstrand ophthalmoscope. Instead of measuring the width of the retinal arterioles on the patient's retina, they are measured on the lens attached to the Gullstrand.

Theodore M. Shapira.

Nicholls, J. V. V. The effect of section of the posterior ciliary arteries in the rabbit. *Brit. Jour. Ophth.*, 1938, v. 22, Nov., pp. 672-687.

This article represents a re-evaluation of the findings of Wagenmann

some 45 years ago, Krückmann in 1899, and Capauner in 1893. Gonin, Nettleship, Greeves, and others, since 1902, have suggested that a choroidal vascular disturbance is the underlying cause of pigmentary degeneration of the retina. Wagenmann produced such degeneration by section of the posterior ciliary arteries. In the experiments now reported the Wagenmann technique was followed as closely as possible. Young adult rabbits were used, the twenty eyes operated on being for the most part pigmented. The method employed is fully described. Wagenmann's results in producing pigmentary degeneration of the retina by section of the posterior ciliary arteries are confirmed. Nevertheless, the results of the present experiments do not confirm the vascular theory of causation of retinitis pigmentosa, but, on the contrary, evidence was found against such a theory. (Illustrations, tables, references.)

Orzalesi, F., and Cassuto, N. Sympathol action on the pressure of the central artery of the retina. *Boll. d'Ocul.*, 1938, v. 17, April, pp. 270-278.

The chemistry of this synthetic product resembles that of adrenalin. Its pharmacodynamic action was tested in twelve patients by conjunctival instillation or by the hypodermic route, with the idea of learning its behavior on retinal arteries. The age of the patients, seven of them males, varied from 20 to 38 years. Sympathol provoked a lowering of retinal blood pressure which manifested itself ten minutes after the injection and reached its maximum after thirty minutes. After two hours the pressure had returned to the original level. In two of the cases no appreciable variations were noted. For instillation a ten-percent solution was

used, and the results were the same. In no case was an increase of pressure noted. In a case of intracranial hypertension the retinal pressure showed no variation. (Bibliography, 2 figures.)

Prado, D. L. do. Thrombosis of the central retinal vein secondary to dental infection. *Rev. de Oft. de São Paulo*, 1938, 6th yr., April-June, pp. 76-78. (See *Amer. Jour. Ophth.*, 1938, v. 21, Nov., p. 1298.)

Rintelen, F. Remarks on measurements of blood pressure in the retinal vessels. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Oct., p. 14.

Adequate local anesthesia is absolutely essential. Often pressure readings that are too high result from tangential application of the dynamometer because the partially anesthetized eye moves away from the instrument. Careful and deliberate application of the instrument is essential, and it is unnecessary to hurry to avoid changing the intraocular pressure by prolonged application of the dynamometer. Comparative measurements have demonstrated to the author that one may take five to ten seconds for the measurement without significantly modifying the readings. Too rapid a tempo does not allow accurate determination of Fritz's index; that is, the difference between the pressure that causes the first oscillation of the arterial wall and that producing complete collapse. It is of value in judging rigidity of the vessel wall.

Frequently a difference between the diastolic pressure in the right and left eyes is found and is of significance, but conclusions must never be drawn from this finding except when a tonometric reading has been combined with the dynamometric.

metric reading has been combined with the dynamometric.

Measurements in tabetics did not disprove Sobonski's assertion that hypotony is the cause of tabetic optic atrophy. However, the author points out that hypotony cannot be the decisive factor or atrophy would be observed frequently in aortic insufficiency.

F. Herbert Haessler.

Schuck, C., and Miller, W. O. Dark adaptation of the eye and vitamin-A storage in young adults. *Arch. of Internal Med.*, 1938, v. 61, June, p. 910.

On examination of 94 female freshman students between the ages of 17 and 22 years, poor dark adaptation was shown in 26.6 percent. Eighteen experimental subjects showed improvement under treatment with vitamin A. Some of the subjects failed to improve under vitamin F. Further studies on the action and uses of vitamin A are advised.

Theodore M. Shapira.

Seidel, E. A very rare retinal disease as partial manifestation of a general hereditary disorder. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 520-525.

Tuberous sclerosis was diagnosed in the case of a fourteen-year-old girl with sluggish mentality and bilateral choked disc. In addition, in the fundus of the right eye, temporal to the optic papilla and about in the horizontal meridian, there were observed two cystic-appearing tumors, each in width about a disc diameter. In the fundus of the left eye, a similar swelling was present just above and temporal to the optic nerve. A reddish-brown slightly elevated spot the size of a pea was present in the forehead near the root of the nose. Similar spots were noted in the middle of the upper part of the left cheek, between the shoulder blades, under the

left scapula, under the left costal arch, and on the flexor surface of the thigh. In the skin of the cheeks were a great number of small, reddish, firm, warty growths of the size of the head of a pin, such as are known as sebaceous adenomata.

H. D. Lamb.

Spaeth, E. B. Etiology of retinal separation considered from the standpoint of surgical correction. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 1046-1070.

This ophthalmologic review includes discussion of history, etiology, retinal tears, mechanics of the formation of retinal tears, retinal separations from direct traumatism, myopia, inflammatory causes, symptomatic separation, and aphakia and retinal separation. The author concludes that the presence of a retinal tear or of a disinsertion is necessary to the development of retinal separation.

J. Hewitt Judd.

Sugita, Yozo. Further observations on the method of spontaneous retinal detachment, particularly the physicochemical factors in its origin. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 561-586.

Physicochemical experiments confirm the author's contention that spontaneous retinal detachment is produced through an increase in osmotic concentration of the fluid vitreous. Water is thereby drawn from the retina, causing it to contract and leading to its detachment. The cleavage products in the fluid vitreous accumulate, according to the Gibbs-Thomson law, at the surface of the vitreous through positive adsorption. By accumulation of the cleavage products upward and temporally, due to centrifugation through movements of the eyeball, retinal tears are most commonly produced in these positions.

H. D. Lamb.

Torres Estrada, Antonio. Vitreous detachment. *Anales Soc. Mexicana de Oft. etc.*, 1938, v. 12, Jan.-July, pp. 151-161.

After eighteen years of blindness from bilateral iridocyclitis with pupillary seclusion, the left eye was operated upon for complicated cataract. After healing, an anterior detachment of the vitreous was found. The author emphasizes the fact that escape of vitreous during cataract extraction predisposes to vitreous detachment.

W. H. Crisp.

Weve, H. J. M., and Fischer, F. P. The clinical value of proteolytic ferments in the subretinal fluid. *Ann. d'Ocul.*, 1938, v. 175, Nov., pp. 807-813.

The authors studied 118 cases of retinal detachment. In 87 percent the subretinal fluid did not contain appreciable quantities of proteolytic ferments which would attack fibrin. Increased proteolysis was present in fresh cases, cases tending to have complications, and cases of disinsertion with cyst formation. Increased proteolysis is not compatible with formation of rigid adhesions, but there is no definite correlation between proteolytic content of the subretinal fluid and the final operative result. The best prognosis is had when the proteolytic activity of the vitreous is normal, that is, just enough to prevent formation of vitreous bands without attacking the adhesive formations between the retina and choroid.

John M. McLean.

Weve, H. J. M., and Fischer, F. P. Deterioration of albuminoid substances in the detached retina. *Ann. d'Ocul.*, 1938, v. 175, Nov., pp. 823-828.

The subretinal fluid contains not only ammonia but amines, derived from retina or choroid. In the detached retina

there is a deterioration of albuminoid substances. Since the oxygen consumption does not correspond to proteid combustion, the deterioration must be by proteolysis. This appears to be related to anatomic lesions in the retina, particularly the tear. Toxicity of the subretinal fluid seems to be due to substances which arise following the alteration in metabolism. The normal retina, which performs glycolysis far in excess of oxidation, presents neither albuminoid deterioration nor proteolysis. Thus it is seen that detachment, although curable, produces serious changes in the vital processes of the retina.

John M. McLean.

Weve, H. J. M., and Fischer, F. P. The importance of p_H in the proteolytic activity of the subretinal fluid and its inhibition. *Ann d'Ocul.*, 1938, v. 175, Nov., pp. 813-816.

The p_H of subretinal fluid falls with the duration of the detachment. There is no correlation between the proteolytic capacity of the subretinal fluid and its p_H , but there is a correlation between inhibition of proteolysis and p_H . As the p_H falls, proteolysis is increasingly inhibited, and this explains the decreased activity in old detachments.

John M. McLean.

Weve, H. J. M., and Fischer, F. P. Metabolism of the detached retina. *Ann. d'Ocul.*, 1938, v. 175, Nov., pp. 817-823.

Normal retina in contact with its pigment epithelium has a very low oxidation-reduction potential (maximum of r_H 16 to 18). Detached retina is strongly oxidized (r_H 21 to 25.5). This oxidation is due to alteration in metabolism, with respiration, not glycolysis, predominating. Glycolysis is

only possible when the retina is in contact with its pigment epithelium. Detachment interrupts contact, with consequent oxidation, inactivation of the glycolytic ferment, and loss of vision. Reattachment reverses this process.

John M. McLean.

Wynkoop, E. J., and Hadley, L. Schüller-Christian's disease. *Arch. of Pediatrics*, 1938, v. 55, July, p. 417.

The authors report a case in a child two years and nine months old, with the classical symptoms of bony defects in the skull, diabetes insipidus, and exophthalmos. The authors noted improvement in the condition when X-ray therapy and proper diet were used.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Carroll, F. D., and Goodhart, Robert. Acute alcoholic amaurosis. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 797-803.

Four cases of total but temporary blindness associated with acute poisoning due to ethyl alcohol are reported. All were characterized by total blindness in both eyes, normal pupillary reaction to light and convergence, normal fundi, and rapid improvement after withdrawal of alcohol. The reasons for considering this disease as a manifestation of acute poisoning with ethyl alcohol are discussed, and evidence is presented to show that methyl-alcohol poisoning among addicts is of rare occurrence. Addiction is probably a prerequisite. Although infrequent, this disease demands correct etiologic diagnosis because of the excellent prognosis as compared with the poor prognosis in cases of blindness due to methyl-alcohol poisoning. J. Hewitt Judd.

Heim, H. Therapy in tabetic optic atrophy. *Wiener med. woch.*, 1938, Nov. 12, p. 1196.

After a short review of the literature, the author tells of many cases in which after treatment with iodine there was no progress in the atrophy after many years.

Theodore M. Shapira.

Hill, T. R. Some aspects of neuromyelitis optica. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 143.

A case report is given and conclusions from other cases are cited, to show that progressive bilateral retrobulbar neuritis is not uncommon in disseminated sclerosis. It is possible to find practically identical cases with all degrees of combination of signs and symptoms, between neuromyelitis optica and disseminated sclerosis. The author concludes that progressive bilateral retrobulbar neuritis is a special type of disseminated sclerosis, the "neuromyelitic type."

In discussion Gordon Holmes felt that classification should depend rather on the pathologic conditions underlying the cases, and that with this in mind the two conditions could be differentiated by modern cytopathologic methods.

Beulah Cushman.

Kampmeier, R. H., and Jones, E. Optic atrophy in pernicious anemia. *Amer. Jour. Med. Sciences*, 1938, v. 195, May, p. 633.

The authors discuss three cases of pernicious anemia with optic atrophy. The diagnosis of tabes dorsalis had previously been made in two of the cases. The authors have decided that optic atrophy in pernicious anemia is an intrinsic degeneration rather than directly due to ischemia. Early recognition

of visual disturbances in anemia is essential.

Theodore M. Shapira.

Ridley, Harold. Aplasia of the optic nerves. *Brit. Jour. Ophth.*, 1938, v. 22, Nov., pp. 669-671.

The rare condition reported herein occurred in an only child aged one year, observed in Rupert Scott's clinic at the Royal London Ophthalmic Hospital. The history shows no ocular defect in either paternal or maternal lines. No further defect, mental or otherwise, existed in the case, although such deformities have been noted in the few similar cases recorded. In the case here reported, while the pupils were inactive to light they varied in size unaided by stimulus. The media were clear, the fundi peculiar (illustrated), the red reflex pale with the choroidal pattern well marked. The eyes were quite normal as to anterior appearances. A deep excavation occupied the place of the optic disc, and from its base minute threads representing retinal vessels were all that emerged. A trace of blood, which faded out after leaving the edge of the excavation, was observed in the lower branch of the right eye only. This is stated to be the only case of its kind on record except one in a cat, in which only one eye was abnormal. (Illustrations, references.)

Waldmann, Béla. Parallel study of the pathogenesis of rhinogenous optic neuritis and of serous iritis. *Amer. Jour. Ophth.*, 1939, v. 22, Jan., pp. 44-53.

Wexler, D., and Last, M. Coloboma of the optic nerve and of the macula; a microscopic study. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 787-796.

The authors review the literature and report the case of a woman aged 40

years in whom the right eye revealed a hypertensive retinitis and the left highly myopic eye presented a coloboma of the optic nerve. The eye was removed six hours after death from hypertensive and renal disease, and was sectioned serially. The anomaly was found to be essentially a coloboma of the nerve at its entrance, the nerve being replaced by rudimentary retinal tissue. Associated with this were persistence of remnants of the hyaloid system, widening of the scleral canal, dislocation of the lamina cribrosa, and a choroidal macular coloboma. While the presence of rudimentary nerve tissue may indicate ingrowth of primary retinal layers into the optic stalk, no microscopic explanation could be found for the relation of the undifferentiated nerve to the widening of the optic canal and distortion of the associated structures. J. Hewitt Judd.

Wolff, Eugene. Some aspects of the anatomy of the optic nerve-head. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 70.

An interesting color plate of a section of the optic nerve-head, stained with Mallory's phosphomolybdic-acid and hematoxylin, shows the connective tissue formation of the posterior portion of the lamina cribrosa and the glial structure of the more anterior fibers. The "central connective-tissue sheath" and the intermediary tissue of Kuhnt are discussed, as well as the blood supply of the disc.

VISUAL TRACTS AND CENTERS

Aliquò-Mazzei, Alessandro. Ocular manifestations in tumors of the cranial base of pharyngeal origin. *Boll. d'Ocul.*, 1938, v. 17, March, pp. 180-194.

A man of 51 years was affected by intense pain in the territory of the right trigeminus, internal deviation of the right eye from paralysis of the abducens, anesthesia of the cornea, and neuroparalytic keratitis of two months duration. The radiographic examination showed opacity of the sphenoid bone and disappearance of the foramen ovale. A woman of sixteen years showed the following symptoms: severe neuralgic pain in the territory of the left trigeminus nerve, total ptosis of the left upper lid, total ophthalmoplegia (chemosis, and central ulcer of the cornea with complete anesthesia of the cornea and of the territory of the first and second branches of the trigeminus. Radiographic examination showed slight opacity of the sphenoid with dilatation of the foramen ovale. There was atrophy of the optic disc. A woman of 47 years complained of acute pain of the left side of the face, ptosis of the left upper lid, paralysis of all the external muscles, and anesthesia of the first and second branches of the trigeminus. Radiographic examination showed deep erosion of the sphenoid bone. The writer discusses symptomatology, course, diagnosis, pathology, and therapy, the diagnosis lying in some cases between neoplasm and a basal meningitis of luetic or tuberculous origin. (Bibliography.)

Melchior Lombardo.

Allen, T. D., and Carman, H. F., Jr. Homonymous hemianopsic paracentral scotoma. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 846-849.

The literature is reviewed and the case of a woman aged 48 years presenting this condition is reported. This type of defect, not so rare as formerly believed, is characterized by sudden onset of a defect in the visual field in persons

otherwise healthy, complaints of difficulty with reading and fixation, normal ophthalmoscopic findings, unaltered visual acuity, and good prognosis as to visual acuity. The condition may be easily overlooked unless a careful history is obtained and perimetric examination made of the central fields.

J. Hewitt Judd.

Bujadoux. Transitory reflex monocular blindness following artificial pneumothorax. *Bull. Soc. d'Ophth. de Paris*, 1937, May, p. 334.

There was loss of the superior field within thirty minutes and complete blindness in five days, with retention of consensual pupillary reflex. There were no fundus changes except slight pallor of the disc. The fields and vision slowly improved, so that two months later the only abnormality was a small paracentral scotoma. The possibility of a reflex retrobulbar angiospasm causing edema of the optic nerve is suggested.

Harmon Brunner.

Kalt, Puech, and Kreba. A case of optic chiasmal arachnoiditis following a contusion without wound in the region of the right upper lid. *Bull. Soc. d'Ophth. de Paris*, 1937, May, pp. 291-298.

An arachnoiditis of the chiasm which developed into a serous meningitis. Vision in the right eye was affected within 24 hours; after three months it was reduced to 0.2. An intermittent absolute scotoma and an absolute paracentral scotoma which later became constant developed in the right eye. Four months after onset, vision in the left eye fell to 0.2 with a relative central scotoma, symmetric with that of the right eye, giving bitemporal paracentral scotoma. Surgery gave prompt

improvement in vision. One year from onset the only sequelae were a small paracentral absolute scotoma in each field and a relative central scotoma in the right eye, reducing vision to 0.4. Prompt surgical intervention is stressed.

Harmon Brunner.

Lemoine, A. N. Lesion of the optic tract, probably the result of infected sphenoid sinuses. *Arch. of Ophth.*, 1938, v. 20, Dec., pp. 966-973., also *Trans. Amer. Ophth. Soc.*, 1938, v. 36.

A man aged 39 years had developed hypertrophy of the prostate at the age of 33 years, and impotency at the age of 37 years. Administration of anterior pituitary extract was followed by improvement, but a lesion of the right optic tract developed and progressed to complete loss of central vision in 21 days. The vision was temporarily improved by the use of ephedrine in the nose. After the sphenoid-sinus disease was corrected by operation, the vision and field rapidly improved to normal. At operation the right sphenoid sinus, which was anomalous in that it extended into the posterior clinoid process back of the optic chiasm, was found to have a hemorrhagic area on the posterior wall. Its close proximity to or possible contact with the superior portion of the right optic tract was thought responsible for the retrobulbar neuritis at this point.

13

EYEBALL AND ORBIT

Brain, W. R. Neurological and general medical causes of exophthalmos. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 27.

The causes of exophthalmos are reviewed.

Cashell, G. T. W. **Case of proptosis due to carcinoma of the antrum.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 48.

A case report is given from a series of eighteen cases, four of which had carcinoma of the antrum. It is concluded that in this group proptosis meant involvement of the ethmoid cells, secondary to orbital cellulitis, and that the prognosis was good if radium therapy was instituted early, but bad if proptosis was present.

Beulah Cushman.

Cawthorne, Terence. **Ear, nose, and throat aspects of the differential diagnosis of the causes of exophthalmos.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 19.

Pathologic conditions of the ear, nose, and throat may produce exophthalmos either by causing increase in the orbital contents or by reducing the size of the orbit. The latter may occur either from foreign material being forced into the orbit, from interference with venous return, from extension of inflammation, or from invasion by new growth. Final diagnosis must always be greatly influenced by the radiographic report. Beulah Cushman.

Doggart, J. H. **Differential diagnosis of proptosis in children.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 32.

The eye and orbit at birth and during childhood being smaller relatively than in the adult, proptosis appears earlier, and the eye itself is more distensible. Increased contents of the orbit will cause prominence, as increased size of the eye in myopia, buphthalmia, or cystic tumors. Inflammatory exudates or hemorrhages from injury or blood

dyscrasias may cause prominence. Tumors involving the orbit or its contents are not uncommon in children. Graves's disease is very uncommon but does occur. Weakened support of the eyeball may be a factor, or diminution of orbital volume as in oxycephaly.

Beulah Cushman.

Ellison, J. **Arteriovenous aneurysm.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 43.

Three cases are reported. In the first, arising out of a motorcycle accident, ligation of the internal carotid stopped pulsation and bruit, but the eye later showed retinal hemorrhages of thrombotic origin. In the second case, a tine of a pitchfork had passed between the eyeball and the orbital wall. Ligation of the internal carotid produced relative recovery, although the bruit could still be heard on auscultation. In the third case, due to a fall from a bicycle, the aneurysm ruptured, and the patient died after artificial respiration had been maintained for many hours following ligation of the common carotoid.

Beulah Cushman.

Griffith, A. D. **Pulsating exophthalmos after injury.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 41.

In 20,000 admissions to the surgical wards of Westminster Hospital two cases of pulsating exophthalmos after head injury were included. One case report followed a motorcycle accident in which multiple fractures occurred including fracture of the base of the skull. After temporary ligation of the left internal carotid, pulsation of the eyes ceased at once and the exophthalmos began to recede. The artery was ligated permanently three days later, and the patient recovered.

Beulah Cushman.

Hayes, W. M. Collapse of glass eyes. *Industrial Med.*, 1938, v. 7, Dec., p. 734.

The author reviews the literature and reports a case. He shows that the eye collapses and does not explode, and that it is the posterior, concave portion that gives way.

George A. Filmer.

Knapp, Arnold. Orbital hyperostosis; its occurrence in two cases of meningioma of the skull. *Arch. of Ophth.*, 1938, v. 20, Dec., pp. 996-1005. also *Trans. Amer. Ophth. Soc.*, 1938, v. 36.

The literature is reviewed with special reference to tumors of the sphenoid ridge and tumors of the sylvian cleft. In the first case reported there was unilateral bony deformity with exophthalmos, no changes in the optic nerve in the early stage, and slight paresis of the external rectus muscle. The meningioma involved the squamous portion of the temporal bone, the large wing of the sphenoid bone, and the outer and upper walls of the orbit. The eye was enucleated and as much as possible of the mass in the orbital cavity was removed. After nearly two years the bony swelling measured about 8 by 6 by 4 mm. The pain was relieved entirely by roentgen treatment. In the second case the meningioma apparently originated at the temporal half of the fissure of Sylvius and involved the greater wing of the sphenoid bone and the temporal part of the lesser wing, extending to the anterolateral part of the frontal and the anterior part of the temporal bone. The patient was given roentgen treatment and the process remained stationary. Whether this was due to the roentgen treatment could not be determined. (Photomicrographs.)

J. Hewitt Judd.

MacCallan, A. F. Differential diagnosis of the causes of exophthalmos. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 50.

By the use of pathologic distinctions the author considers acute inflammatory exophthalmos under the headings of simple orbital edema, orbital subperiosteal abscess, and orbital cellulitis.

Beulah Cushman.

Moore, R. F. Differential diagnosis of causes of exophthalmos. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 3.

The author analyzed 117 consecutive cases of proptosis as to bilaterality, direction of proptosis, palpation of orbital contents, limitation of movements, chemosis, traumatic causes, callus formation, hemorrhage into the orbital cavity, inflammatory causes, Graves's disease, dermoid cysts, benign tumors, tumors of the optic nerve and its sheath, primary malignant growths, metastatic growths, arteriovenous aneurysms, thrombosis in the cavernous sinus, and the proptosis of oxycephaly.

Beulah Cushman.

Pochin, E. E. Lid-retraction and exophthalmos in Graves's disease. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 39.

In comparing the apparent exophthalmos of Graves's disease with proptosis the author found that retraction of the upper lid was frequently present without exophthalmos and the lower lid stood at a slightly higher level relative to the cornea before prominence could be measured. In one case this was true for a year before the exophthalmos could be measured. In other cases of Graves's disease there was no lid retraction but a measurable exophthalmos. Thus the author concludes that

exophthalmos and lid retraction in Graves's disease give an illusion of exophthalmos. Both widen the palpebral fissure, exophthalmos widening it downward and exposing sclera below the cornea, while lid retraction widens it upward, exposing sclera above the cornea.

Beulah Cushman.

Rushton, R. H. The clinical measurement of the axial length of the living eye. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 136.

The author used the shadow cast by a metal object between an X-ray tube and the eye, because such a shadow is visible in the dark with the closed eye after dark adaptation. The principle is to find the distance between retinal X-ray perception at the posterior pole and a ribbon of light passing tangentially to the cornea in a plane exactly parallel with that at the posterior pole. A suitable piece of apparatus was demonstrated.

Beulah Cushman.

Whiting, M. H. Orbital meningo-encephalocele. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 58.

Anterior encephaloceles emerge between the ethmoid and frontal bones at the expense of the horizontal plate of the ethmoid. In the orbit they pass between the frontal process of the frontal bone, the lacrimal bone, the cribriform plate of the ethmoid, and the nasal process of the superior maxilla. Posterior encephaloceles emerge between the sphenoid and the frontal bone on either side of the lesser wing of the sphenoid. Parsons' classification of cysts of the orbit is given. He calls encephalocele an inclusion cyst of congenital origin.

A number of case reports are in-

cluded. Operative interference terminated fatally in a number of instances, from subsequent meningitis. The presence of pulsation transmitted from the cranial cavity, and the occurrence of pressure symptoms such as restlessness, vomiting, and slowing of the pulse on compression of the tumor, are given as the clearest indications of the nature of an encephalocele.

EYELIDS AND LACRIMAL APPARATUS

Cornet, Emmanuel, Dacryocystorhinectomy (a new technique). *Ann d'Ocul.* 1938, v. 175, Nov., pp. 842-845.

The operation follows the Dupuy-Dutemps technique until the nasal mucous membrane is exposed. Then a large window is cut out of the mucosa and a corresponding window from the side of the lacrimal sac. The edges are joined with two continuous catgut sutures forming a circular anastomosis. The nasolacrimal duct is curetted and the skin and canthal ligament are closed in the usual manner.

John M. McLean.

Focosi, M. Malformations from persistence of the oblique fissure of the face. *Boll. d'Ocul.*, 1938, v. 17, April, pp. 255-269.

A girl of sixteen years showed an anomaly of the left side of the face. The internal canthus was about 7 mm.

lower than the right one. The palpebral fissure, instead of being horizontal, was oblique. There was ectropion of the margin of the lid in its nasal portion, with eversion of the lacrimal punctum. There was also a deepening of the nose-chin line, and the left ala nasi appeared to be 1.5 cm. higher than the right. Etiology and pathogenesis are discussed, and plastic surgery for the condition is described. (Bibliography, 5 figures.) Melchior Lombardo.

Fonseca, Aureliano. The Marcus-Gunn syndrome. *Rev. de Oft. de São Paulo*, 1938, 6th yr., April-June, pp. 92-100.

Description of a case of jaw-winking, with discussion of its anatomic basis. W. H. Crisp.

Guy, Loren. Simple dacryocystorhinostomy. *Arch. of Ophth.*, 1938, v. 20, Dec., pp. 954-957.

The incision is made from a point 3 mm. above the inner canthal ligament downward and outward, just nasal to the anterior lacrimal crest, and is carried down to the bone through the periorbita. The latter is then elevated temporally, exposing the lacrimal fossa and the sac. In the lower half of the fossa a window about 4 by 6 mm. is made by means of a chisel, a pair of scissors, or a curette. The nasal mucous membrane and the corresponding portion of the sac wall are excised, the tissues allowed to fall back into their natural position, and held in place by a pressure bandage. No sutures are used. Of the 54 patients operated on by this method, fifty were relieved both of epiphora and of empyema of the sac. One failure was due to faulty technique and one resulted from nasal obstruction due to neglected sinus disease. J. Hewitt Judd.

Michail, D., Vancea, P., and Zolog, N. Investigations on the lacrimal elimination of glucose. *Bull. de l'Acad. de Méd. de Roumanie*, 1938, v. 5, no. 2, p. 182.

Glucose is not normally eliminated in the tears, but is found in the tears of diabetics, and during the course of alimentary and adrenalin hyperglycemia. In the former two conditions, there is no relation between the amount of glucose excreted and the blood-sugar level, while the contrary seems to be true in the latter condition. George A. Filmer.

Nicholls, J. V. V. A case of granuloma of the lacrimal canaliculus. *Canadian Med. Assoc. Jour.*, 1938, v. 39, p. 569.

A pea-sized tumor surrounding the upper canaliculus in a 60-year-old woman was removed and studied pathologically. Because of its microscopic appearance and the presence of some old conjunctival scars, the lesion was assumed to be of a trachomatous nature. (Illustration.)

George A. Filmer.

Rabinowicz, M. G. Chronic bilateral dacryoadenitis. *Viestnik Ophth.*, 1938, v. 13, pt. 1, p. 112.

In a woman of nineteen years, enlargement of the lacrimal glands was associated with enlargement of the thyroid. The diagnosis was made by biopsy. The tissue was excised from the lids, with complete recovery.

Ray K. Daily.

Raverdino, Emilio. A turbinotome for dacryocystorhinostomy "ab externo." *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 499-503.

The author describes an instrument for biting off a portion of the turbinate

in the external operation of dacryocystorhinostomy. It is a forceps, curved in a slight S-shape, its ends cup-shaped, 7 by 4 mm. The edges are only slightly sharpened. The plane of the spoon-shaped end of the instrument is parallel to the plane of the handles. The author finds numerous uses for the instrument in the operation mentioned. (3 figures.)

Eugene M. Blake.

Smith, J. W. **Blepharitis comb.** Arch. of Ophth., 1938, v. 20, Oct., pp. 658.

For removing the densely adherent scales in ulcerative blepharitis a comb has been devised which consists of eight metallic needles 3 mm. long, covering a width of 3 mm.

J. Hewitt Judd.

Thurel, Robert. **The motor disturbances of the lids.** Arch. d'Ophth. etc., 1938, v. 2, Sept., p. 795, and Oct., p. 897.

After discussing the physiology of the lid movements the pathology of lid motility is gone into at great length. The various headings and subheadings are: paralysis of the orbicularis (of peripheral and central origin), paralysis of the levator, hypertonic retraction of the upper lid, involuntary movements, and blepharospasm (of peripheral and central origin). The article does not lend itself to abstracting.

Derrick Vail.

Tomkevich, A. I. **Late results of external dacryocystorhinostomy.** Viestnik Ophth., 1938, v. 13, pt. 3, p. 388.

A review of the literature and an analysis of the author's own material, which consisted of 414 operations, with 96.14 percent final satisfactory results. In the author's experience recurrences appear within the first few months after

the operation, and he urges that patients be kept under observation for six months.

Ray K. Daily.

Valière-Vialeix. **Additional cases of chronic conjunctivitis provoked by mycelian infections in the lacrimal canaliculi.** Bull. Soc. d'Ophth. de Paris, 1937, May, p. 298.

Reports of two proved cases which presented as chronic monocular conjunctivitis. The author gives the characteristic symptoms as: conjunctivitis predominating at the inner canthus, with folliculosis in chronic cases; abundant stringy conjunctival secretion; and itching at the inner angle. The canaliculi could be irrigated. The cases were resistant to conjunctival medication. The treatment is careful curettage after incision of the canaliculus.

Harmon Brunner.

White, J. P., Michaelson, I. C., and Heggie, J. F. **Tumor of lacrimal sac of cellular mixed parotid type, associated later with tumor of parotid region of same histological character.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 159.

A mass in the region of the left lacrimal sac, which had increased in size after sixteen years, was removed. The growth was hard and fibrous, but no disease of the bone or other structures was noted. A course of deep X-ray therapy was given. Four months later a swelling was found at the upper pole of the parotid, and because of enlargement it was removed two months later. Histologically the tumors were similar. Each had a thin capsule and was moderately vascular. The intimate relation of stroma and cells characteristic of mixed parotid tumors was observed in both tumors.

15

TUMORS

Angius, Tullio. Lymphangioma of the limbus. *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 538-542.

The author reviews our knowledge of this rare tumor of the eye. Many believe it is congenital, for it often increases rapidly at puberty. Trauma may play a part. He reports an instance of the condition in a man of 63 years. One year before Angius saw the patient a small growth had appeared at the limbus of the right eye. After eight months this was removed but no study was made of it. The growth recurred within four months and increased rapidly. Microscopic study showed a collection of oval spaces, lined by endothelium and separated by connective tissue septa. There was some infiltration by polynucleated cells. Fibroblasts were found in the septal positions. The growth raised the corneal epithelium but did not invade Bowman's membrane. (2 figures.)

Eugene M. Blake.

Bietti, Giambattista. Precocious choroidal metastases of latent primary carcinomas and their diagnostic problems. *Boll. d'Ocul.*, 1938, v. 17, March, pp. 163-179.

A man of 65 years had an intraocular tumor which upon microscopic examination was found to be carcinoma. The same symptoms developed in the other eye a year later. A woman of 32 years was affected by symptoms of intraocular tumor of the left eye, which was found to be a carcinoma of the choroid. The same symptoms manifested themselves in the other eye, which was found to contain the same type of tumor. Both these patients passed away with abdominal symptoms. In

both cases the two eyes became affected by a tumor which appeared to be metastatic, and before the metastases the patients had not noticed any subjective general disturbances, nor did the clinical and laboratory examinations reveal the localization of the original focus of the neoplasm. The diagnostic difficulties are discussed. (Bibliography, 6 figures.)

Melchior Lombardo.

Braun, Reinhard. Chaoul's concentrated-fractional roentgen near-radiation of malignant tumors of the lids. *Klin. M. f. Augenh.*, 1938, v. 100, Oct., p. 557.

Chaoul's method combines the advantages of application of radium with those of soft roentgen rays. Eleven cases are reported, three unfavorable. Good results are obtained with sufficient dosage. The danger from radiation is reduced if a nickel-plated lead prosthesis is used for protection of the healthy surroundings.

C. Zimmermann.

Braun-Vallon. A case of optic-nerve tumor. *Bull. Soc. d'Opht. de Paris*, 1937, May, pp. 287-290.

A three-year-old child had deviation of the right globe downward, exophthalmos, and unilateral papilledema, with roentgen signs of enlargement of the optic foramen. Exploration revealed an encapsulated tumor encircling the optic nerve. This was resected, leaving the globe. The pathologic diagnosis was meningoblastoma, type sarcomatous with involvement of the optic nerve. It is considered as a slowly progressive benign growth rarely involving cranial portions of the optic nerve.

Harmon Brunner.

Dupuy-Dutemps. Tumor of the choroid. Liver metastasis eight years

after enucleation. *Bull. Soc. d'Opht. de Paris*, 1937, May, p. 284.

Case report of a 33-year-old male whose left eye was enucleated for melanosarcoma of the choroid. Invasion of the sclera but no perforation was found on microscopic examination. Observation over five years showed no local or general return. Two photomicrographs compare sections of the primary and metastatic tumors. Another case is cited with metastasis nine years after enucleation.

Harmon Brunner.

Herman, P. Melanotic sarcoma of iris associated with congenital anomaly. *Bull. Soc. d'Opht. de Paris*, 1937, no. 3, March, p. 164.

Report of a case of melanoma occurring in a heterochromic iris on a large, presumably congenital ectopia. (2 photomicrographs, pathologic report.)

Harmon Brunner.

Keller, P. Glioma of the retina at Tonkin, thirteen observations histologically confirmed. *Arch. d'Opht. etc.*, 1938, v. 2, Sept., p. 813.

Various statistics give the frequency of retinal glioma as 6.8 per 100,000, 17 per 100,000, 10 per 100,000. The author reports a frequency at Tonkin of 26 per 100,000, 23 percent of the cases being bilateral. Of the thirteen cases reported, in six the tumor had broken through the eyeball and fungated externally between the lids. Five showed ocular hypertension of rapid evolution, generally present at the end of two months after the condition was first recognized. Enucleation or evisceration was performed in all except two of the cases. After the stage of hypertension is reached radiation treatment does not work. None of the cases gave a history of heredity. (Illustrations.)

Derrick Vail.

Lijo Pavia, J. The formation of retinal folds by pressure on the globe from an orbital tumor. *Rev. Oto-Neuro-Oft.*, 1938, v. 13, May, p. 122. (See *Amer. Jour. Ophth.*, 1938, v. 21, Sept., p. 1068.)

Radnot, Magda. Carcinoma of the meibomian glands. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 95, Oct., p. 22.

In a 59-year-old man, a resistant thickening of the lid occurred and gradually increased in size in the course of seven months. Histologically it proved to be a medullary carcinoma. Tumors of the meibomian gland are very rare and are more often adenoma than carcinoma. The rare carcinoma may be very malignant, and may recur, metastasize, and cause death.

F. Herbert Haessler.

Rosenbaum, H. D. Sarcoma of the iris. *Amer. Jour. Ophth.*, 1938, v. 21, Dec., pp. 1360-1364.

Sédan, Jean. Recurrence of epithelioma of the limbus, with large independent palpebral and corneal attachments. *Ann. d'Ocul.*, 1938, v. 175, Nov., pp. 829-836.

Ten years ago an epithelioma of the limbus and adjacent cornea had been excised but not irradiated. Eight years later a similar mass arose from the palpebral conjunctiva, and later it bridged across to become attached at the site of the former tumor on the cornea. The two attachments were entirely independent, for a probe could be passed under the tumor mass between these two areas. Excision was again practised.

John M. McLean.

Sgrosso, S. Diagnosis of metastatic carcinoma of the eye. *Rassegna Ital. d'Ottal.*, 1938, v. 7, July-Aug., pp. 439-498.

The author describes minutely four cases of metastatic carcinoma of the eye, in two of which there were bilateral manifestations. A third case was monocular and the fourth was probably localized in the optic nerve behind the globe. The ages of three patients were between 50 and 60, while one was only 38 years old.

The literature is carefully reviewed and the different phases of the subject fully discussed. The author found 258 cases reported, 70 percent of which were in females. The age most frequently affected is between 50 and 60 years. The tumor reaches the eye through the blood stream and lodges in the choroid. Approximately 25 percent of the cases are bilateral, and when both eyes are affected there is usually only a short interval of time between them. Metastasis in the eye occurs anywhere from one to two years after the primary growth is discovered. The first symptom is usually loss of vision or defect in the visual field. Commonly the ocular growth is in the posterior portion, usually near the disc and more often on the temporal side. The tumor is flat and ovoid at first, the color yellowish gray. The tension is not raised except late in the disease. In differential diagnosis one must consider simple detachment, sarcoma, and irritative glaucoma. (5 colored figures.)

Eugene M. Blake.

Shepkalova, V. M. Diktyoma of the retina. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 95.

Clinical and histopathologic report of a case in an eight-year-old girl. This malignant tumor arises from embryonic retina. Histologically it is differentiated from glioma by its mitoses, which are placed on the free surface of the cellular layer, away from connective tissue

and blood vessels. In glioma the mitoses are located basally. Ray K. Daily.

Torres Estrada, A. Dermoid cyst of the orbit penetrating to the anterior cerebral fossa. *Anales de la Soc. Mexicana de Oft.*, etc. 1937, Oct., Nov., and Dec., pp. 105-108.

The patient was a woman of 62 years. Since the first years of her life she had had a small induration between the upper orbital margin and the left eye, toward the outer end of the eyebrow. The growth had increased in size since the age of 45 years. The eyeball was greatly displaced forward, downward, and inward. Puncture of the tumor showed a thick yellowish oily liquid, without suppuration. After incision above the eyebrow and separation of the ocular tissues from the orbit, the growth was found to be of the size of a small orange. The roof of the orbit had undergone destruction, and the growth had penetrated into the anterior cerebral fossa, pushing before it the dura mater. After evacuation of the fluid, the sac was dissected out. The eyeball returned to its normal position.

INJURIES

Berezinskaja, D. I. The rôle of paracentesis in the treatment of chemical ocular burns. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 361.

A report of a laboratory study on rabbits. The conclusions are that repeated paracentesis is helpful in moderately severe alkali burns, and in severe corneal burns provided the conjunctiva was not destroyed. In necrosis of the conjunctiva paracentesis is helpful only in conjunction with mucous-membrane transplantation. Ray K. Daily.

Bonnet and Bonamour. **An unusual case of cataract caused by electrocution.** Bull. Soc. d'Opht. de Paris, 1937, May, p. 333.

Three months afterward, the patient had a superficial anterior cortical cataract of the left eye with vision of 0.5. Six months later a posterior cortical cataract developed and reduced vision to 0.02. The need for guarded prognosis in these cases is stressed.

Harmon Brunner.

Ciotola, Guido. **Two cases of double rosette cataract.** Rassegna Ital. d'Ottal., 1938, v. 7, July-Aug., pp. 504-520.

The author cites two cases of rosette cataract, which were unusual in that the rosettes were doubled; that is there was an anterior subcapsular rosette-shaped opacity and also a similar one in the posterior subcapsular region. Both cases occurred in young men and resulted from rather severe contusions. The development of the opacities is explained as forming about the original Y-shaped figures, with extensions to bundles of fibers attached to the sutures. In all about 150 such cases have been described. The literature is reviewed and cases abstracted. (4 figures.)

Eugene M. Blake.

Denig, Rudolph. **Indications for immediate transplantation of buccal mucous membrane for eye burns.** Med. Record, 1938, v. 148, Dec. 7, p. 395.

Immediate surgical treatment of the majority of eye burns by mucous-membrane transplantation is urged by the author. He shows that burns, even if some distance removed from the cornea, may damage the capillaries of the limbus and interfere with the nutrition of the cornea. Excision of limbal conjunctiva with transplantation of buccal mucous membrane results in formation

of new capillaries, hyperemia, and increased diffusion of nutritive material into the corneal tissue. (Illustrations.)

George A. Filmer.

Disler, H. H. **Rosette-shaped traumatic cataract.** Viestnik Opht., 1938, v. 1, p. 5.

From a study of traumatic opacities, the course of which is recorded by drawings, the author divides the lenticular traumatic manifestations into immediate, secondary, and late. The primary changes are associated with injury to the lens capsule and lens substance, appear at the site of injury, and consist in destruction of lens fibers and edema. They may be arrested at any point of their development and may regress to some extent. The pathogenesis of secondary lenticular changes is less clear. They are usually in the form of rosette-shaped cataracts which may completely regress. Late opacities may appear months after the injury and usually proceed to complete opacification. The author's group of opacities, appearing after injuries not involving the lens, are characterized by their persistence. Five posterior ring-like opacities and one anterior-capsular opacity showed no change during a period of observation extending over several months. Two cases with posterior and anterior subcapsular opacities were practically without change for three weeks. In none of these cases was there a rosette-shaped opacity.

Ray K. Daily.

Dollfus, M., and Borsotti, I. **Experimental study of tolerance to intraocular foreign bodies of rustless steel or non-magnetic alloys.** Arch. d'Opht. etc., 1938, v. 2, Oct., p. 911.

From their clinical and experimental observations the authors reach the fol-

lowing conclusions: (1) The presence of an oxidizable metal, iron, steel, or copper, within the eye provokes by its chemical nature a severe disorder which leads to rapid loss of vision and irremediable retinal lesions. (2) Rustless steel, on the contrary, more and more employed in industry, is tolerated like any other inert chemical body, such as glass, within the eye. Siderosis does not result. (3) Every effort must be made therefore to determine the nature of the intraocular metal before operating. If it is rustless steel or non-magnetic alloy it is wiser to refrain from attempting extraction, because experience has shown that the eye supports the foreign body without damage. Such a foreign body is only dangerous by carrying infection or by traumatic lesions it may have provoked. (Illustrations, bibliography.)

Derrick Vail.

Filippov, H. A. Electromagnetic service. *Viestnik Ophth.*, 1938, v. 13, pt. 2, p. 276.

The author urges mass production of giant and hand electromagnets for the purpose of equipping all ocular dispensaries with them. Ray K. Daily.

Goldberg, H. K. Iodism with severe ocular involvement. *Amer. Jour. Ophth.*, 1939, v. 22, Jan., pp. 65-68.

Hartmann, Karl. The question of ocular lesions from sulphuretted hydrogen. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 510.

Numerous reports show that sulphuretted hydrogen damages the corneal epithelium primarily (not by the way of the blood and respiration), causing a superficial punctate keratitis, with complete recovery after a few days. As deviating from this, the author has previously described a case of typical

keratitis with complete loss of sensibility, a combination not hitherto mentioned in the literature. A similar observation was made by Kiel in a caisson worker, with subsequent scars of the cornea and vision 8/10 after several months. Experiments in rabbits proved that 0.1 per 1000 of sulphuretted hydrogen might after prolonged action produce superficial and also deep keratitis. In the numerous cases of acute and subacute poisoning by sulphuretted hydrogen described in the literature, ocular affections are never mentioned. Such a case of severe acute poisoning without ocular involvement is now presented.

C. Zimmermann.

Jacqueau and Dumas. Subconjunctival hemorrhage from strangulation. *Bull. Soc. d'Ophth. de Paris*, 1937, May, p. 341.

Strangled by a neckerchief caught in transmission gears, the patient suffered no immediate aftereffects. Twenty-four hours later he developed a tremendous ecchymosis of the entire conjunctiva, a moderate ecchymosis beneath the surrounding skin, and slight exophthalmos. The reason for delay in development of the hemorrhage is discussed.

Harmon Brunner.

Kalt, M. E. The harmful action on the retinal pigment epithelium of certain solutions containing iodides and injected parenterally. *Bull. Soc. d'Ophth. de Paris*, 1937, May, p. 304.

Following reports of pigmentary degeneration from massive parenteral injections of fortified Pregl's solution (Septoid), the author reports a series of animal experiments. Believing sodium iodate (NaIO_3) to be the active agent, he injected a 4-percent solution into gray rabbits and produced, as injections were continued, retinal edema

and pigment spots of different forms and degrees. Histologic sections showed pigment cells invading the retina, and greater dosage caused retinal and choroidal degeneration. No other ocular lesions were observed. (5 illustrations, 4 references.)

Kaplan, I. D., and Lapidus, A. M. Occupational acrichinin keratitis. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 409.

Workers in factories producing this product develop, in addition to symptoms of general intoxication, a keratitis characterized by edema, erosions, and a greenish-yellow discoloration of the cornea. Relief from the subjective symptoms is rapid, but the discoloration and corneal dullness may remain for two months. Ray K. Daily.

Kochkongov, M. I. A serous cyst of the iris. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 268.

A report of a case which developed fifteen years after an injury.

Ray K. Daily.

Kolen, A. A., and Triumfov, A. V. A rare case of hysteria. *Viestnik Opht.*, 1938, v. 13, pt. 1, p. 38.

After a fall from a moving train a woman had paralysis of the third and sixth nerves. Soon afterward she developed severe pain in the left eye, relieved only by pressure on the eyeball. On release of pressure the pain extended over the entire head and the patient became ataxic. When the patient again presented herself at the hospital two years later, the left eye was in a state of enophthalmos, atrophy, and hypotony. With constant pressure over the left eye the patient had no complaints, but release of pressure brought on severe pain and ataxia. The patient

begged to have the left eye enucleated, and recovered promptly after the operation. The author considers the patient's difficulties hysterical, and attributes the hypotony, enophthalmos, and atrophy of the left eye to the prolonged continuous pressure. Ray K. Daily.

Lijo Pavia, J. Traumatic hole at the macula and detachment of the vitreous. *Rev. Oto-Neuro-Oft.*, 1938, v. 13, p. 154.

A thirteen-year-old boy sustained a macular hole from a blow on the eye. The foveal lesion was first noticed one month after the injury. Six months after the injury the author noted detachment of the vitreous between disc and fovea. The evolution of both macular and vitreous changes is described in great detail. A discussion of macular holes and the factors which may produce them is appended. (Illustrations.)

McAlester, A. W., III. Gonioscopy as an aid to localizing small foreign bodies in the anterior chamber. *Amer. Jour. Ophth.*, 1938, v. 21, Dec., p. 1380.

McDonald, Robb. Carbon disulphide poisoning. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 839-845.

The author reviews the literature and presents the results of his studies of 120 workers employed in a rayon industry where they had been exposed to carbon disulphide for a long time. Many showed systemic signs of chronic intoxication, and 75 percent of those examined had some ocular complaint. The most significant early ocular sign was enlargement of the blind spot. Diminution of the corneal reflex was found in over one half of the workers. Diminution of the pupillary reaction to light was the second most common finding. The ocular signs of carbon-

disulphide poisoning are essentially those of a systemic neurologic disturbance. No cases of rayon keratitis were seen.

Makhlin, I. M. Injury to the eye from eyebrow and eyelash dyes. *Viestnik Opht.*, 1938, v. 13, pt. 2, p. 271.

A report of three cases, two of which were promptly cured by irradiation with Bucky's border rays. The author urges supervision of beauty parlors and of the sale of the dyes.

Ray K. Daily.

Plitas, P. S. Occupational ocular injury with a bobbin from a weaving machine. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 412.

A blow on the eye by a bobbin flung from a weaving machine is among the most serious occupational injuries. It should be entirely eliminated by industrial prophylaxis. Within the last four years the author has seen thirteen such injuries, in nine of which the eyes were finally enucleated. The vision of the four cases in which the eyeballs were saved was 0.7, 0.1, 0.02, and 0.001 respectively.

Ray K. Daily.

Teulières, M., and Beauvieux, J. Post-traumatic pearl cyst of the iris. *Arch. d'Opht. etc.*, 1938, v. 2, Aug., p. 706.

As a rule traumatic penetration of a cilium into the anterior or posterior chamber leads to a severe inflammatory reaction. Occasionally, however, the cilium may be well tolerated and after a long time become encysted, resulting in so-called "pearl cyst" of the iris. A case is described in which such a cyst developed within a year after a perforating steel injury and retention of a cilium in the anterior chamber. The rapid evolution is explained by proliferation of the ectodermal cells of the

ciliary bulb, or by corneal cells being drawn into the anterior chamber at the time of the accident. (Illustrations, bibliography.)

Derrick Vail.

Tichvinskii, B. T. The use of egg membrane in plastic operations on the eyeball. *Viestnik Opht.*, 1938, v. 13, pt. 3, p. 397.

The author uses eggshell membrane to prevent development of symblepharon in chemical burns and in recurrent pterygium. He emphasizes the importance of suturing the membrane in the desired place.

Ray D. Daily.

Woschke, Joachim. Retinal detachment and accident. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 587.

Accidental detachment may occur after perforating injuries, from formation of holes and tears in the retina, from intense loss of vitreous and later inflammation followed by formation of cyclitic pseudomembranes, even long after the injuries. It may also occur after direct contusion of the eyeball if a tear of the retina is produced, or after indirect contusion of the globe by impact on the skull or whole body (by formation of retinal tears). Another cause is excessive bodily exertion.

C. Zimmermann.

17

SYSTEMIC DISEASES AND PARASITES

Brückner, A. Physiologic and clinical ophthalmologic problems in relation to individual variability. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 541-568; Nov., pp. 726-756; and Dec., pp. 913-953.

The reactions of different individuals to normal and abnormal stimuli vary within a wide range. The individual variability is based on the constitution as determined by heredity. Persons with extreme degrees of insufficiency

are able to exist at low intensities of light only with the protection which human civilization affords. The author reviews the theories of color sense and discusses the dependence of color sensation on the stimulus. Recent findings support the hypothesis of Hering that the peripheral nerve endings respond to stimulation by the production of chemical substances of antagonistic character, acetylcholine and epinephrine.

Congenital color deficiencies are discussed under the topics of partial color blindness, anomalous trichromates, diagnosis and frequency of different types of color deficiency, heredity of color deficiency, total color blindness, and the development of color sense. The phenomena of local adaptation are discussed with reference to the phenomena of revulsive local adaptation, including black sensation and the importance of contrast; local differences in adaptation, especially as to measurement of this phenomena; the phenomenon of constancy; and the seat of local adaptation.

The third section discusses normal and pathologic light and dark adaptations and variation in the relative thresholds, the various factors causing individual variation, and the diseases accompanied by disturbances of dark adaptation. The individual variabilities found by clinical methods are discussed under the headings of focal illumination, tonometry, and sensitiveness of the cornea. Under diseases of the eye dependent on constitution, the author discusses tuberculous diseases of the eye and scrofula of the eye. The diseases of the eye discussed in relation to weather and climate are hordeolum, catarrhal ulcer of the cornea, acute conjunctivitis, herpes corneae, scrofula of the eye, and acute glaucoma.

J. Hewitt Judd.

Caramazza, F. Experimental tuberculosis of the eyeball from inoculation with attenuated bacilli of human tuberculosis. *Boll. d'Ocul.*, 1938, v. 17, March, pp. 133-152.

The author injected into the anterior chamber of one eye and the vitreous of the other eye of four rabbits an emulsion of human tubercle bacilli in different concentration. One rabbit was injected in one eye with tubercle bacilli while the other eye had been inoculated some time before with the aqueous of another rabbit affected by active tuberculosis. The inoculation in the anterior chamber was followed by no reaction at the beginning, and the presence of tuberculous formations in the iris and ciliary body was noted as a late manifestation. The inoculation in the vitreous was followed by a slight diffuse inflammatory process, with foci of exudate between choroid and retina and later in the anterior uveal tract. At a still later stage the specific character was lost. This is taken as a demonstration of the natural tendency to exhaustion of the tuberculous process due to the action of the natural powers of defense. The rabbit which was inoculated with tubercle bacilli while the other eye was affected by a tuberculous process showed Koch's phenomenon, namely, the development of an acute reaction leading to panophthalmitis. (Bibliography, 11 figures.)

Chesney, A. M., Woods, A. C., and Campbell, A. D. Observations on the relation of the eye to immunity in experimental syphilis. *Jour. Exper. Med.*, 1939, v. 69, Jan. 1, p. 163.

It is known that second inoculations of homologous strains of *Treponema pallidum* made after the ninetieth day following the original infection are not

followed by a secondary infection, an acquired resistance having apparently been set up. In this investigation, syphilitic rabbits were allowed time to develop an acquired immunity, as shown by the fact that one control group failed to develop lesions following intracutaneous injection of infective material. Injections into the cornea or anterior chamber, however, resulted in lesions in 62 percent of the animals tested, although showing a longer incubation period than in control animals. The authors conclude that in the syphilitic rabbit the eye does not participate to the same extent as other tissues in the general resistance which develops during the course of the infection. A statement of the necessary tests, in Portuguese.

Denig, E. P. Considerations on the present diffusion of trachoma in Cordoba. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, April, p. 182.

The article consists chiefly of a statistical analysis. The author reaches the conclusion that about 2.7 percent of the population of the province are affected, but that the disease is decreasing in incidence. Edward P. Burch.

Esser, A. M. Ascetic self-blinding. *Klin. M. f. Augenh.*, 1938, v. 101, Oct., p. 580.

Quotations from the legends of ascetic self-inflicted destruction of the eyes in Christian and Indian cultures show common traits, while absence of this psychologic phenomenon in antiquity illustrates the difference of mentality of these groups.

C. Zimmermann.

Ferree, C. E., and Rand, G. Prescribing light. An important factor in the care and treatment of the eye. *Brit. Jour. Opht.*, 1938, v. 22, Nov., pp. 641-668.

It is the opinion of the authors that, in comparison with other branches of medicine, the use and progress of hygienic measures in the care and treatment of the eye have been overlooked to the point of undue neglect. The subject of hygiene is therefore dealt with in this lengthy article (not lending itself well to abstract) under the following headings: important structural and functional conditions, outstanding features in lighting in relation to examination and care of the eye, means for improving lighting conditions, examination of the eye in relation to lighting, intensity of light and strength of reading glasses. The prescribing of light to meet the needs of individual persons is now a practical possibility, and it is the feeling of the authors that, when properly used, such practice will be of definite service. (References.)

D. F. Harbridge.

Friedenwald, Harry. The services of the Jews to ophthalmology. *Acta. Ophth. Orientalia*, 1938, v. 1, Sept., pp. 36-48.

This is a comprehensive review of the part played by Jewish physicians in the field of ophthalmology since the Arabic period. Many familiar names of workers of the middle ages and of recent centuries are briefly referred to. The history of modern ophthalmology in Europe includes the names of Hirschberg, Magnus, Stilling, Axenfeld, Bernheimer, Salzmann, Hirschmann, Laqueur, and Javal. Among prominent American Jewish ophthalmologists may be mentioned Hays of Philadelphia, Gruening of New York, and Koller (discoverer of the anesthetic properties of cocaine).

NEWS ITEMS

Edited by DR. H. ROMMEL HILDRETH
640 S. Kingshighway, Saint Louis

News items should reach the Editor by the twelfth of the month

DEATHS

Dr. Anton Schwartz Schneider, Plattsburg, New York, died November 19, 1938, aged 48 years.

Dr. Benjamin Franklin Baer, Jr., Philadelphia, died December 19, 1938, aged 59 years.

Dr. Oscar Merle Shirey, Cleveland, Ohio, died November 20, 1938, aged 60 years.

MISCELLANEOUS

Approximately 15 percent of all blindness can be traced to syphilis, says the National Society for the Prevention of Blindness in a statement urging widespread public observance of National Social Hygiene Day on Wednesday, February 1.

"The venereal diseases—syphilis and gonorrhea—are among the major destroyers of sight," the statement points out. "For that reason, we have a special interest in the efforts to control these diseases, and we are glad to cooperate with the campaign sponsored by the American Social Hygiene Association.

"The importance of this problem may be realized from the fact that about 60,000 babies are born with congenital syphilis every year. Most of them develop a serious eye condition at some time in early life, unless they receive adequate medical care.

"Prenatal syphilis is preventable if the expectant mother who is infected begins treatment in the early months of pregnancy. The Society advocates a routine blood test for every expectant mother, because such a test can usually determine the presence of syphilitic germs.

"The compulsory use of prophylactic drops in the eyes of all babies at birth has brought about a marked reduction in the amount of blindness from gonorrheal infections; and a great decrease in the amount of blindness from prenatal syphilis can be achieved also.

"In industry, too, the eye hazards are greater when workers are suffering from syphilis. The

presence of this disease increases the severity of eye injuries; a little cut or bruise of the cornea, that would otherwise pass unnoticed, may develop into a serious condition if the worker is suffering from syphilis.

"The consequent lowering of sight to a point of economic blindness carries with it the full indemnity for complete loss of vision; and the courts have held that the existence of syphilis does not lessen the responsibility of the insurance carrier unless it can be definitely shown that the loss of sight would have progressed even if the injury had not occurred."

The National Society for the Prevention of Blindness has announced that Lewis H. Carris, managing director, assumed the title of general director on January 1, with Mrs. Winifred Hathaway as associate director. Mrs. Eleanor Brown Merrill, an associate director for the past five years and formerly secretary of the Society, becomes executive director, and will relieve Mr. Carris of administrative details. John M. Glenn, one of the founders of the National Society for the Prevention of Blindness, has been elected an honorary vice-president.

The Department of Ophthalmology at the University of California, a year ago, received the sum of \$40,000 for the establishment of the Charles Taylor Reeve Foundation in Ophthalmology. Just recently, with Mrs. Reeve's death, an additional \$30,000 has been added to this fund. The interest from this combined fund is for the study and treatment of diseases of the eye.

The Seventeenth Annual Summer Graduate Course in Ophthalmology and Otolaryngology, Denver, Colorado, is announced for July 24 to August 5, 1939. The Denver Graduate Course, pioneer of its kind in the country, was originally conceived to supply a two-fold need of instruction and summer recreation. This year it is intended to make the work even

more attractive by bringing a larger number of guest instructors and adding evening lectures to the curriculum. The evening lectures will be delivered by prominent and qualified leaders in the allied specialties, who will bring the latest information in their fields as it relates to ophthalmology and otolaryngology. For further information write Dr. Harry L. Whitaker, 1234 Republic Building, Denver, Colorado.

Mr. L. Vernon Cargill, November, 1938, opened the reconstituted pathological and research department of the Royal Eye Hospital. The foundation of the department 50 years previously was pointed out, and the good work done there. The new extension will increase the possibilities of the department.

SOCIETIES

The Ophthalmological Society of the United Kingdom will convene at the Royal Society of Medicine on April 20, 21, 22, 1939. The subject for discussion will be "The problems of refraction." The Bowman Lecture will be delivered by Professor Weve on "Diathermy in ophthalmic practice." The International Organization against Trachoma and the International Association for the Prevention of Blindness will hold their annual meetings on April 19, 1939.

The Puget Sound Academy of Ophthalmology and Otolaryngology announces the following officers: Dr. J. Edward Clark of Seattle, president; Dr. W. A. Cameron of Tacoma, vice-president; Dr. Purman Dorman of Seattle, secretary-treasurer.

The Eye Section of the Philadelphia County

Medical Society, presented the following program on February 2, 1939: Sarcoma of stump of the iris eight years after iridectomy with cataract extraction, by Dr. Maxwell Herman; Iritis due to gout, by Dr. Jacob Reber; Mirror writing in school children, by Dr. M. E. Smukler. Discussions were given by Dr. Samuel Bruck and Dr. Samuel J. Goldberg.

PERSONALS

Miss E. E. Cass has been appointed Hon. Ophthalmic Surgeon to the New Sussex Hospital for Women and Children at Brighton, while Mr. Joseph Minton has been elected Assistant Ophthalmic Surgeon to the West End Hospital for Nervous Diseases.

At a dinner meeting of the Cleveland Ophthalmological Club, held November 1, 1938, the guest speaker was Dr. Ramon Castroviejo of New York City. Dr. Castroviejo gave a most instructive and illuminating talk on "Plastic surgery of the cornea." The lecture was illustrated with beautiful lantern slides and moving pictures.

Dr. Gilbert Patterson of Santa Rosa, California, announces the removal of his office to 1116 Mendocino Avenue.

Dr. Hans Barkan of San Francisco has recently returned from a four months' trip abroad. A good deal of his time was spent in Switzerland, where he made some interesting observations.

Dr. Otto Barkan of San Francisco has recently returned from an extended trip abroad, most of his time having been spent in the Scandinavian countries.

LECTURES ON MOTOR ANOMALIES*

VIII. PARALYSIS OF INDIVIDUAL EYE MUSCLES: ABDUCENS-NERVE PARALYSIS

A. BIELSCHOWSKY, M.D.

Hanover, New Hampshire

By far the most frequent isolated paralysis of an ocular muscle is that of the external rectus. It is due to the fact that the abducens nerve has a longer course on the base of the skull than both the other motor nerves of the eyes, and is exposed to injuries more than the others, particularly where it passes around the apex of the petrosal portion of the temporal bone. In recent abducens pareses the diagnosis is easily made from the restriction of the outward ocular movement, the uncrossed diplopia due to the convergent position of the visual lines, and the increase and decrease of the separation of the double images according to whether the eyes are moved either to the paretic or the other side. But exceptions to the typical behavior occur rather frequently and may render the diagnosis more difficult. These may be caused by different factors; first, by the behavior of the antagonist of the paretic muscle which, as was mentioned before, may or may not develop a secondary contracture and change the typical features of the paretic deviation in such a way that they become more or less similar to a nonparetic strabismus.

Sometimes one encounters cases which display all the symptoms of an abducens-

nerve palsy, with the sole exception that the homonymous double images are not on the same level and that they are slightly inclined toward one another. This may be due either to a complication of the abducens-nerve palsy with a concomitant hyperphoria or paresis of one of the vertical motors, or the muscle plane of the external rectus may not coincide with the horizontal meridian of the eye. One may assume the last-mentioned factor to be the cause if the vertical and rotary components of the deviation are rather small in comparison with the horizontal component, and if only the latter increases or decreases in the typical manner according to the direction of gaze. The other components of the deviation may represent a subordinate (secondary) function of the paretic muscle and its antagonist, due to their asymmetrical adjustment to the eyeball. The secondary contracture of the antagonist will either outlast the paresis if it is based on an organic change of the structure of the internal rectus, or it may represent only a transitory stage if the deviation is based on an increased tonus of the internal rectus; if it subsides gradually, the deviation will decrease until binocular vision is restored.

The congenital deficiencies of abduction need special discussion because of their rather frequent occurrence and the peculiarities they present when compared with ordinary pareses of the abducens

Fig. 26 (Bielschowsky). Congenital deficiency of abduction. A, in looking straight ahead no deviation whatever, binocular single vision. B, the left eye does not respond to the levoversion impulse. C, retraction syndrome takes place in dextroversion: high degree of enophthalmos and narrowing of the palpebral fissure of the left eye.

nerve. The main characteristics of congenital deficiencies of abduction are as follows:

1. In more than 60 percent of the cases, a total lack of abduction is to be found in the left eye, in 16 percent it is in the right, and in 24 percent in both eyes.

2. Sixty percent of the patients are of the feminine sex.

3. Besides the lack of abduction there is a deficiency of adduction in 50 percent

4. In spite of a complete lack of abduction the majority of the patients have binocular single vision owing to an habitual turning of the head to the side of the deficient abduction.

5. There is a striking contrast between the unilateral total lack of abduction and the very small paralytic deviation which, in many cases, is hardly noticeable, even when the head and gaze are in the primary position. Only exceptionally, one meets with extremely high deviations due either to a maximal contracture of the internal rectus muscle, or to the presence of abnormal fibrous tissue in the place of that muscle and fixing the eye in a strongly adverted position (fig. 27).

6. In most cases diplopia is absent, due either to unilateral amblyopia, which occurs not infrequently or—much more frequently—to binocular single vision, which is achieved by the habitual (vicarious) position of the head, the movement of which makes up for the absent movement of the eye.

7. In quite a few cases the congenital deficiency of the lateral movements is combined with an upward deviation that takes place when an impulse to an adversion is given, just as has been described in the discussion of the so-called overaction of the inferior oblique. In some cases of the former group a faulty development of the internal rectus has been found. Its tendon was divided into two branches, one being inserted in the

Fig. 27 (Bielschowsky). Extremely high deviation in a case of bilateral congenital deficiency of abduction due to abnormal tissue in place of the internal recti muscles.

of the cases. The deficient adduction is combined, as a rule, with a more or less marked retraction of the eyeball and a narrowing of the palpebral fissure ("retraction syndrome"). (Fig. 26.)

horizontal meridian but behind the equator so that it acted as a retractor bulbi, while the other branch was inserted in the upper half of the sclera near the insertion of the superior rectus.

8. Most striking features are presented

been found in patients who had been operated upon. In most of them the deficiency of the ocular movement was due to a faulty development or a complete absence of the muscles. In place of the external rectus was found a nonelastic

Fig. 28 (Bielschowsky). Congenital bilateral deficiency of abduction combined with bilateral facial paralysis. A, no paralytic deviation in the primary direction of gaze. B, Bell's phenomenon most impressive.

by patients with a congenital bilateral deficiency of abduction and bilateral facial paralysis. Bell's phenomenon as well as the complete immobility of the face are most impressive (figs. 28A, B and 29A, B, C).

9. In many of these congenital deficiencies of ocular movements other congenital anomalies have been ascertained:

fibrous band, either without any or with only very few muscle fibers. Its incapacity, both to relax and to contract, and, furthermore, the resistance it offers to the contraction of the internal rectus accounts for some of the characteristics of the congenital anomalies such as the missing, or very small paralytic deviation; the lack or insufficiency of adduction; and

Fig. 29 (Bielschowsky). Same anomaly as shown in previous figure. A, no deviation in looking straight ahead. B, eyes respond to any lateroversion impulse with a maximal convergence; C, Bell's phenomenon very marked.

either a poor development or a complete absence of the thyroid gland, epicanthus, unusually marked asymmetry of the halves of the face, and other abnormalities.

The peculiarity of the clinical phenomena in cases with congenital deficiencies of ocular movements is to be attributed to anatomic irregularities, which have

the retraction phenomenon. The narrowing of the palpebral fissure in cases with the retraction syndrome is an accessory phenomenon accompanying the retraction of the eyeball to which the lids remain attached. In some cases the external rectus may be found to be fairly normal, while in place of the internal rectus there is a nonelastic band, resisting active as

well as passive outward movement of the eyes, that is held in convergent position without being able to turn in to the normal extent. In other cases of the anomalous

ses, I can state that isolated trochlear palsies occur at least half as often as abducens palsies. Most statistics give too small a number of trochlear palsies, ob-

Fig. 30 (Bielschowsky). Torticollis of ocular origin in a case of right trochlear paresis. A, binocular single vision with head tilted toward the left shoulder. B, maximal vertical deviation with the head tilted to the right.

lies under discussion, a faulty development of the motor nerves and their nuclei has either been found—for instance, an aplasia of the sixth and seventh nuclei in cases of congenital bilateral paralysis of the sixth and seventh nerves—or must be assumed.

As to the therapeutic procedures in congenital motor anomalies, there is no need for operation if binocular single vision in the central part of the field of fixation can be attained by a slight turning of the head. In other cases with either a disfiguring paralytic squint or an anomalous position of the head, operations cannot be dispensed with. They will be discussed together with the treatment of paralytic squint.

PARALYSIS OF THE TROCHLEAR NERVE

By far the most frequent and important type of paralysis of a single vertical motor is trochlear-nerve palsy—most important because not infrequently there are variations which lead to a wrong diagnosis. From my material comprising several thousand cases of ocular paraly-

ses, I can state that isolated trochlear palsies occur at least half as often as abducens palsies. Most statistics give too small a number of trochlear palsies, obviously because frequently these palsies are not recognized or are misconstrued. The most striking sign in many cases is habitual torticollis; that is, a tilting of the head toward one shoulder. The ocular origin of torticollis is often not recognized, especially in cases of congenital trochlear-nerve palsy or those acquired in early childhood (fig. 30A, B). The general practitioner or the surgeon who is first consulted about torticollis frequently takes it for a contracture of the sternocleidomastoid muscle, although there is neither a contracture which can be felt nor a resistance to the passive straightening of the head or to its being tilted toward the opposite side.

I have observed many such cases in children who had to endure various kinds of orthopedic treatment for several years, naturally without the least effect. As soon as the physicians or the parents discontinued the forced straightening of the child's head, it was tilted toward the same side as before the treatment. At last the physician advised the parents either to punish the child because of the "bad habit" or to divide the sternocleidomas-

toid muscle. But when the operation was done, the child did not cease to tilt the head, as before. In several cases the child's mother was the first to discover the ocular origin of the position of the head by observing that the child closed one eye during the forced upright posture of the head, whereas both eyes were opened as soon as the child was allowed to keep the head tilted in the habitual way. This observation was correct: The habitual position of the head helped the child to secure binocular single vision, whereas to avoid a disturbing diplopia arising from straightening the head the child closed one eye. These children discard the anomalous position of the head spontaneously as soon as the balance of the vertical motors of the eyes is restored by the required operation, which I shall discuss later.

The ocular origin of this kind of torticollis was first recognized by Cuignet,¹ in 1873; he could not, however, explain the connection between the ocular disorder and torticollis any more than could Landolt² in 1890, in his paper on ocular torticollis. Without knowing the problem under discussion, A. Nagel³ in 1871 had supposed that in cases of slight paresis of an elevator or depressor muscle a vertical and rotary deviation would be caused by tilting the patient's head toward one side, a supposition based on the discovery that a parallel rotation of the eyes around the visual axis is produced by tilting the head towards the opposite side. As we now know, parallel rotation of the eyes is due to a reflex innervation of vestibular origin. The parallel rotary movement could only be performed, as Nagel presumed, by both the inferior muscles of one eye (inferior rectus and inferior oblique) and at the same time by both superior muscles of the other eye (superior rectus and superior oblique). The combined action of the two superior

muscles as well as that of the two inferior muscles cannot cause a deviation of one of the visual lines provided the two muscles of each pair are equally strong, for in that case the antagonistic components of those muscles will compensate each other and there can result neither a vertical nor a lateral deviation of the visual axis. The only effect of the combined action of these two muscles is the rotary movement which they produce in the same direction.

Let it be supposed that in a case of right trochlear-nerve palsy the head is tilted toward the right shoulder. From this will arise a vestibular excitation of those muscles that are able to produce a parallel rotary movement of the eyes to the left. This movement is produced in the left eye by the two inferior muscles, and in the right eye by the two superior muscles. The paralyzed right superior oblique muscle can no longer compensate the elevating and adducting component of the right superior rectus, from which a vertical and a lateral deviation of the right visual line must result, whereas in a normal person both the visual axes would be stationary. And what will happen if the head of the patient with the paretic right superior oblique muscle is tilted toward the left side? Both inferior muscles of the right eye and the superior muscles of the left eye receive the vestibular innervation to rotate the eyes around the visual axis to the right. This movement can be performed without the coöperation of the paretic muscle; hence no deviation of the visual axis will result. As mentioned before, the more the sound muscles are burdened the more favored will be the paretic muscle. Now one can understand the reason for the habitual tilting of the head that is observed in so many cases of trochlear-nerve palsy: If the head is tilted toward the shoulder of the sound side, a coöp-

Fig. 31 (Bielschowsky). Head-tilting test in a case of bilateral trochlear paresis. A, while the patient's head is erect, two images of the fixed black stripe are seen, the lower one belonging to the left eye (reproduced to the right of the figure). B, the vertical separation of the two images is increased by tilting the head toward the left shoulder. C, the opposite kind of vertical divergence is brought about by tilting the head toward the right shoulder, which makes the paresis of the right trochlear nerve manifest.

eration of the superior oblique muscle is not called for, so that binocular single vision is obtained.

Nagel's supposition has been proved correct by the investigations made by Hofmann and me⁴ in 1900. In that publication the explanation given by other authors concerning the tilting of the head in cases of trochlear-nerve palsy was discussed and proved wrong. But, strange

to say, that wrong explanation has found currency to this day in many later articles on the subject. It is said that the paretic eye, deviated upward by tilting the head, is depressed as far as necessary to bring both visual axes to the same level, so that the vertical distance between the double images is removed and only a small lateral distance remains, which can be easily corrected by a convergence or divergence

innervation. The error of this explanation can be recognized at once. If a prism of 10 degrees, base up or down, is placed before one eye and the head tilted alternately toward either side, the two images will be seen at the same height, but only in respect to the horizontal plane, so that if an effort is made to converge the double images pass each other without meeting. The direction in which they are moving will deviate from the direction in which they are seen moving with the head erect, by the same angle which the basal line of the eyes—that is, the line between both nodal points—includes with the horizontal.

There is another argument against the wrong explanation just mentioned: In cases of nonparetic vertical divergence or of paresis of the superior or inferior muscle the tilting of the head does not influence the distance between the two images. Therefore, this peculiar posture of the head will be found only if the balance of the oblique muscles is disturbed, provided that the patient can get binocular single vision at all.

I have not yet been able to find out why the tilting is of no use in palsies of the vertical recti, although these muscles help to bring about rotation of the eyes around the visual axes necessitated by tilting the head toward the opposite side. According to my experience, paresis of the superior or inferior oblique is in all cases at the bottom of ocular torticollis, provided that only by this posture can binocular single vision be obtained.

It may be stated in brief, that in some cases of trochlear-nerve palsy the habitual position of the head differs from the one just described because the patient chooses the most convenient position of the head that relieves the paretic muscle enough to permit binocular single vision. Cases will be encountered in which the head is

turned toward the sound side, so that the visual line of the paretic eye, because it is now turned out, is not acted on by the oblique muscles. A habitually depressed position of the head in cases of trochlear-nerve palsy is seldom encountered.

For an exact investigation of the influence that the position of the head just discussed exerts in certain cases of vertical deviation, one may use a simple apparatus constructed on the principle of Helmholtz's *Visierzeichen* (fig. 31A, B, C). While the patient's head is fixed by his taking between his teeth the little plate at one end of the rod, he looks at a horizontal black stripe on a piece of white cardboard fixed to the other end of the rod 30 inches (75 cm.) away. The rod is put through a short tube, so that when the patient tilts his head it rotates around the same axis and through the same angle as the head. In this way it is insured that the visual line keeps its direction during the tilting of the head, since the cardboard with the fixed stripe keeps pace with the movement of the head, in respect to both the amount and the direction. A patient with a left trochlear-nerve palsy using this little apparatus will see, while his head is erect, two images of the black stripe, the image belonging to the left eye being below the other image and both converging to the left side (fig. 31a). When the head is tilted toward the left shoulder, the vertical distance and the obliquity will increase considerably (fig. 31b), whereas tilting of the head toward the right shoulder makes the two images come to fusion or in a case of bilateral paresis brings about the opposite vertical divergence (fig. 31c).

The deviation caused by a trochlear palsy is made up of several components, the vertical one being the most important in point of diagnostic value. In typical

cases the vertical deviation increases in looking down as well as in looking to the sound side, according to the physiologic function of the superior oblique, which has the main influence on the depression of the eye while the visual line is turned in; whereas, if the latter is turned out, the only effect the superior oblique has on the eye will be an inward rotation of the vertical meridian. Bearing

the latter will appear parallel in the opposite part of the field of fixation where the function of the oblique muscles is confined to the vertical component (fig. 32).

The photograph shows the two images in various parts of the field of fixation in a typical case of trochlear-nerve palsy. The patient is fixating the little lamp in the middle of the tangent scale. By turn-

Fig. 32 (Bielschowsky). Double images (*r* and *l*) of a horizontal object in the various parts of the field of fixation, in a case of right trochlear palsy.

this in mind one has to expect that the vertical distance of the double images will increase in looking down because the paretic eye will lag behind, while in looking up there will be the minimum, if any, vertical diplopia. In looking to the sound side, the disturbance of balance between the oblique muscles will become more and more noticeable: The paretic eye will deviate upward under the influence of the inferior oblique which is not, or insufficiently, counterbalanced by its antagonist. In looking to the paretic side, the vertical position of the paretic eye depends less and less on the oblique muscles. Therefore, the vertical deviation will decrease more the more the paretic eye is turned out. But in that position the loss of the rotary component of the superior oblique will bring about the maximum of obliquity of the double images; whereas,

ing the patient's head, while he is ordered to fixate the lamp continuously, his eyes are made to turn to the left side and the right, up and down, up and to the left or to the right, and so on. The measurement of the various components of the deviation obtained in this way is not very exact but is sufficient for the diagnosis and as basis for comparing the results of later examinations with those of the first.

From what was said about the behavior of the paretic deviation in the various parts of the field of fixation, it is easily understood that a patient with trochlear-nerve palsy will instinctively try to bring the objects that attract his attention into that part of the field of fixation where he will see them singly. He can achieve this either by rotating his head around the frontal axis so that the chin is pressed

against the chest, or by turning the head around the vertical axis toward the sound side. In either case, the object looked at may be seen single since the eyes are brought into a position where the paretic muscle is considerably unburdened. A habitually depressed position of the head in cases of trochlear-nerve palsy is very seldom met with because it is rather inconvenient. More frequently, the head is turned habitually toward the sound side so that the patient looks at an object straight in front with the visual line of the paretic eye averted. But this position of the head will be satisfactory only in cases with very slight trochlear-nerve palsy because it does indeed do away with the vertical deviation, but not with the meridional disclination due to which disturbing diplopia, particularly in reading, may remain, double images of the vertical lines crossing each other at acute angles. Hence, the majority of patients with trochlear-nerve pareses will show a habitual tilting of the head toward the shoulder of the sound side, sometimes combined with a rotation of the head around the vertical axis toward the same side. By that position of the head, the paretic superior oblique is unburdened completely and the patients do not feel any discomfort. It goes without saying, that patients with ocular paralysis will demonstrate an anomalous position of the head only if it relieves them of diplopia. If binocular single vision cannot be obtained by any vicarious position of the head or if unilateral amblyopia prevents a disturbing double vision, the head is held in its ordinary position. Sometimes existing anomalous positions of the head are given up if the paretic deviation increases to an insuperable degree.

As in cases of abducens-nerve palsy, not infrequently trochlear-nerve palsy also gradually loses its typical features by the development of a secondary con-

traction of the inferior oblique muscle, the antagonist of the paretic muscle, while the latter is recovering. In such a case the vertical distance of the two images no longer increases on looking down or decreases on looking up. Changes in the amount of vertical divergence take place only when the patient is looking from left to right; the vertical divergence increases in the direction of the sound side and decreases in the opposite direction, whereas the contrary is found with respect to the meridional (rotary) deviation, just as in the first stage of the paresis. Why does the change in the type of the paresis not extend to the influence of the lateral movements on the vertical divergence, so that the deviation becomes concomitant in the whole field of fixation as in abducens-nerve palsy? The influence of the vertical motor muscles on the position of the eye at a given moment depends on the angle between the visual line and the muscle planes of those muscles. If the visual line is abducted, the oblique muscles have no influence on the vertical position of the eye, whereas their influence increases the more the visual line is adducted. These conditions are not altered when an originally paretic vertical deviation is maintained at a later stage only by a contracture of the antagonist of the paretic muscle. If such a case is encountered and the first stage of the paresis is not known, it is difficult to decide whether the deviation is to be connected, for instance, with a palsy of the left trochlear nerve or with a paresis of the right superior rectus muscle. In either case the behavior of the vertical deviation is the same, increasing if the patient looks to the right and decreasing if he looks to the left. The small lateral component does not matter, as was said before. Not even the obliquity of the two images is sufficient for the differential diagnosis, as has been discussed previously.

In such cases the head-tilting test will help to find the origin of a paresis. The patient observes the two images of the black strip on the cardboard screen. If,

described is similar to that anomaly, previously discussed, which gives the impression of excessive functioning of one or both inferior oblique muscles. The

Fig. 33 (Bielschowsky). A, permanent secondary deviation of the normal left eye in a case of right trochlear palsy. B, upon looking down and to the left the right visual line cannot be lowered at all. C, upon looking down and to the right, however, the right eye does not lag behind the left eye.

for instance, the vertical distance between the two images increases when he tilts his head toward the left shoulder and decreases or disappears when he tilts it the other way, one may conclude that the change in the vertical distance is caused by a disturbed balance of the left oblique muscles, the superior oblique being too weak in relation to its antagonist. If in the head-tilting test vertical distance does not show the aforementioned difference, one may take it for granted that the muscles of the left eye are intact, but the right superior rectus muscle is too weak in relation to its antagonist. Since this test has proved to be true in several hundred cases of the palsy under discussion which I saw before the atypical stage developed, I know that it is absolutely reliable, positive results always indicating that the change in the vertical distance between the images is caused by the oblique muscles.

The atypical vertical divergence just

anomaly in most of the latter cases is congenital and in some of them distinguishable from the atypical vertical deviation due to a secondary contracture of the inferior oblique by an absence of the meridional disclination of the vertical meridians, and sometimes also of a vertical deviation in the primary direction of gaze.

If the paretic eye has better vision or has been dominant since childhood it is used for fixation and the patient presents a permanent secondary deviation of the sound eye. In the photograph (fig. 33A, B, C) the left eye is deviated downward. The deviation disappeared in dextroversion and increased to maximum in levo-version. At first glance one was led to think of a paresis of the left superior rectus, but the next photograph shows that in looking up and to the left both visual lines are elevated equally. That one was dealing with the secondary deviation of the right eye in a case of complete

paralysis of the left superior oblique, was proved by the position of the eyes in the lower part of the field of fixation; moreover, by the positive result of the head-tilting test. The habitual secondary devia-

tion of the nonparetic eye was due to hyperopic astigmatism of the latter. The vision was less than two-thirds of normal, while the paretic eye had full uncorrected vision.

AMERICAN OPHTHALMOLOGY GROWS UP: TURBULENT YEARS FROM 1908-1915*

S. JUDD BEACH, M.D.
Portland, Maine

On January 30, 1938, a medical news story broke in the New York Sunday papers. It rated well over a column on the front page of the Education Section. Judging by the headlines, interest centered in its promise of a curb on the specialists in medicine. It predicted that, by 1940, before they started practice, the qualifications of these specialists would be tested by a national board.

The story was well told, and it properly censured the self-appointed specialist. It did not mention, however, the fact that the ophthalmologists had for years operated just such an examining board; that it was the genius of a few of their leaders that conceived this plan; and that only their careful experience and experiment had made possible the larger scheme, with 12 special boards and a coordinating advisory body. There was, indeed, no mention made of the ophthalmic board, although three of the younger boards were named. The truth of the matter is that in these few years the

perspective has become so blurred that the sharp outlines of events leading up to the movement for examining specialists have disappeared. Only to those of us who have had special interest in the work is the American Board of Ophthalmology more than just one of the many specialty boards—one of the last, in fact, to be recognized by the authorities. Yet it is believed by the men who were interested in this project that, besides being the pioneer in testing specialists, the ophthalmic board has also been the source of the present stir in graduate medical training. If this is a fair statement, it seems only reasonable to claim this new impressive examining structure as a monument to those of our specialty by whose ingenuity and foresight it was conceived 25 years ago. The object of these remarks is to place a modest wreath in their honor.

Records of the period are either lacking or disappointingly discreet. There are, of course, no minutes for the Board itself prior to its organization in 1915. Its circulars simply state that, in 1913, the three national ophthalmologic organizations appointed a joint committee. This committee, after holding various meet-

* Presented at the Seventy-fourth Annual Meeting of the American Ophthalmological Society at San Francisco, California, June 9-11, 1938.

ings, emerged with the project of a joint examining board. As a consequence, in 1915 there was organized what is now the American Board of Ophthalmology. The chronicles of the Board record nothing to suggest that the process was not so simple a one as has just been described. In reality, for a period of years, various groups had been wrestling with unprecedented problems in ophthalmologic sociology. It was by the momentum thus generated that this machinery was set in motion.

The law takes for granted, as medical men know, that any graduate in medicine is qualified, without additional study, to declare himself a specialist. Consequently, at the turn of the century, specialism, and more especially that dealing with diseases of the eye and ear, found itself infested by charlatans. After a severe winter had exhausted the general practitioners, the more prosperous communities would acquire a plague of "mushroom specialists," many of whom had hardly moistened their lips at the Pierian spring.

Those who were interested in this state of affairs during the first decade of 1900 will probably recall three needs: First, to provide facilities for proper graduate training; second, to arrange for testing the qualifications of specialists; and finally, and most difficult, to induce these practitioners to submit to such a test.

The Transactions of the American Ophthalmological Society and those of the Section and the Academy—to use the shorter names for the Section on Ophthalmology of the American Medical Association and for the American Academy of Ophthalmology and Oto-Laryngology—read as though by 1908 ophthalmology had suffered a little colic from its bolus of partly trained specialists.

The chairman's address at the meeting of the Section in 1907 rather exemplifies

the period then closing. It was a discourse of much elegance with the title, "The duality of man." Its unfettered scope is shown by the closing promise to "reveal what spirit is, provided some one would tell what is matter." The following year someone began to tell what was the matter. Fittingly, the speaker was William H. Wilder, of Chicago, for many years afterward the secretary and wise and kindly autocrat of the ophthalmic board. On June 2, 1908, at the First Presbyterian Church in Chicago, in his address as chairman of the Section, Wilder discussed the need for coöperation in the speciality, and that fall, at the meeting of the American Academy of Ophthalmology and Oto-Laryngology, four of the papers were in the same vein. Derrick Vail the elder, in his president's address, said: "It should no longer be possible to be called an oculist after a month or six weeks in a postgraduate school." Vail suggested that a year or two of internship in general medicine, followed by a sufficiently long term in an ophthalmologic institution in America or abroad, should be required, after which he proposed that the student should appear before the proper examining board, one similar to any state board of examination and registration, in order to obtain a license to practice ophthalmology. This plan for a state authority for registration in ophthalmology was suggested repeatedly thereafter. Why it was never adopted was due partly, perhaps, to the difficulty of getting the law enacted. Then, too, with various cults clamoring for recognition, it presented hazards that it may well have seemed wise to avoid.

Laertus Connor, of Detroit, made a startling plea for the teaching of "ophthalmology for students of general medicine." Connor reported that a poll of a county medical society in Michigan showed that the members had never

heard a lecture on refraction, nor been taught how to refract. Most of their eye cases went to opticians. To remedy this condition he advocated that "as much instruction in ophthalmology as possible be given to undergraduates without violence to other courses." They should be enabled to recognize and treat all eye injuries except those concerning intra-ocular foreign bodies; all eye infections; diseases of the uvea; also what he termed simple hyperopia, simple myopia, and simple presbyopia. This was an undisguised attempt to compete with refracting opticians, and will be discussed more fully further on.

Edward Jackson, of Denver, without criticizing Connor's plan, deprecated "teaching the medical student that the crude guessing he can do after the instruction given to large classes in our medical schools will do justice to patients suffering from eye strain." Jackson's suggestion was that when the last year of the medical course is devoted to electives, a sufficient time should be allotted to this kind of work.

Wendell Reber, of Philadelphia, was more outspoken. He said: "Until a man has looked at a thousand eyegrounds . . . his opinion is worse than useless: it is dangerous. Why burden him with half learning a technique that is a waste of time?" Replying to Casey Woods's paper, he said: The refinements of ocular pathology are absolutely postgraduate work."

The chairman's address at the 1909 meeting of the Section at Atlantic City can be regarded as a keynote speech. Alvin A. Hubbell, of Buffalo, though, perhaps, not so original as Wilder, whose remarks had inspired him, "had the knack of selecting the salient points out of even a complicated question and making it clear and easily comprehended by the average reader." Hence it is fortunate

that he chose to assemble and present the diverse topics that were being discussed. Evidently the importance of his inaugural address made a lasting impression, for his biographer for the American Ophthalmological Society made especial mention of it. This reference would be more complimentary if either the subject or the year were correctly stated. Hubbell advocated a required course in ophthalmology for undergraduates, checked by examinations before both the medical faculty and the state licensing board; and for specialists, thorough postgraduate study and clinical work, followed by examination for practice by expert ophthalmologists. He advised that committees be appointed to start proceedings.

This was a remarkably prompt answer to Wilder's call for coöperation, even making allowance for a receptive frame of mind due to threats of outside competition. Of the three activities that followed, two started bravely and failed. The third resulted in the organization of the American Board of Ophthalmology.

1. SIMPLE REFRACTING BY FAMILY PHYSICIANS

To understand the agitation for "simple refracting" requires a picture of its champion. Laertus Connor, of Detroit, previously mentioned, will probably be remembered chiefly for his ability as an organizer. Massive and robust, he was a dominating figure in all medical circles. Besides holding executive offices in most local and state medical organizations, he had served as chairman of the Section on Ophthalmology and as president of the American Medical Association. As founder of the Council on Chemistry and Pharmacy, and as a member of the committee that launched the Journal of the American Medical Association, his influence endures. Connor was a powerful

advocate for any plan he sponsored. He was appointed to the committee to consider the recommendations in Hubbell's chairman's address. With Connor on the committee, it was inevitable that it would recommend his plan for teaching ophthalmology to undergraduates and general practitioners.

By 1910 it emerged as the Committee on Family Physician Refracting. That Connor was appointed chairman was not surprising. The committee's report envisioned a refracting army of 130,000 doctors, thus, according to them, covering an estimated group of 180,000,000 human eyes. On analysis it is clear that the statistician responsible for these figures was in error. Nevertheless, the committee had accomplished no mean task. Thus, they had approached all the state boards; they claimed to have persuaded four, those of Nebraska, Michigan, Vermont, and Utah, to make a knowledge of refraction one of the requirements for a license to practice medicine; to have secured endorsement of the plan by periodicals, including the conservative *Boston Medical and Surgical Journal*, and by General Gorgas, the president of the American Medical Association. In Connor's own state of Michigan a license was being granted only to applicants who could "demonstrate upon living subjects with simple spherical lenses their working knowledge of refraction." Charles A. L. Reed, ex-president of the American Medical Association, called this the logical remedy for the optometric evil. The House of Delegates endorsed the appointment in every state of a committee to coöperate with the national committee on Family Physician Refracting. In many states, including Maine, this committee was actually appointed. During the following year Laertus Connor died, and the whole elaborate structure vanished. It did not simply fall to pieces for there were no pieces left, it sank without a ripple!

2. OPTOMETRY COMMITTEE

Mystery surrounds the 1908 report to the Section by Wilder and Lucien Howe, of Buffalo, who comprised the Committee on Legislation Concerning Opticians. There are no records of their recommendations except that they were referred back for revision. Instead of presenting this revision, the following year the committee requested to be discharged. The reason given was that the members had been made chairmen of other important committees and could not give the necessary time to this one. John C. Bossidy, of Boston, and James Thorington, of Philadelphia, were thereupon appointed, without evasion, as a Committee on Optometry. Their report to the 1910 meeting advocated "no recognition and no compromise" and was accepted. The committee also persuaded the Section and the House of Delegates, in which Bossidy represented the Section, to express their disapproval of ophthalmologists serving on boards with opticians in examinations for licenses in the mechanical examination of eyes. Similar action was also taken by the American Ophthalmological Society. Bossidy's committee was discharged at its own request in 1912, having compiled the *American Medical Association Bulletin on Optometry*. It is unnecessary to state that opposition to optometry assayed almost total loss. When the agitation ceased, the result was the recommendation to introduce a restraining clause into optometry bills. The report written by Wilder, as chairman of the Optometry Committee of 1913, recommending this was not fully concurred in by his associates, Edgar S. Thomson, of New York; E. C. Ellett, of Memphis; John Green, Jr., of Saint Louis; and Hiram Woods, of Baltimore; the latter the Section chairman. The clause prohibited the sale of lenses to persons with defective vision, squint, or diseased eyes without a physician's prescription, and

precluded the use of the title "doctor." It was a variant of the "Jackson" clause, used effectively in Colorado and Maryland.

3. GRADUATE EDUCATION

Jackson had been adroitly swinging the feeling against the optometrists behind his struggle for improving ophthalmologic training. In 1911 he read a paper at Los Angeles on "The optometry question and the larger issue behind it." He first punctured the slogans used so devastatingly by the optometrists in their struggle for recognition. One still remembered is, "A lens is not a pill." "No more," declared Jackson, "is a hypo syringe a pill, or a thermometer, or a knife." He then proceeded to upbraid the ophthalmologists for the predicament they had gotten themselves into. This was the larger issue. "The most important thing that the medical profession has to do is to provide adequate teaching for ophthalmology. Failure properly to perform this duty to the public," he charged, "is responsible for the optometry question."

The first effect on the meeting was to arouse indignation against optometrists, and especially against those general practitioners who, by sending patients to the optometrists, were responsible for the disastrous neglect of emergencies like glaucoma and brain tumors. Finally, F. Park Lewis, of Buffalo, brought the discussion back to the subject of education by saying that "we are never going to get rid of optometry by simply opposing it."

Year by year Jackson's efforts increased in effectiveness. His paper of 1911, just mentioned, had persuaded the Section and the House of Delegates to pass a resolution that, as ophthalmology requires certain subjects not demanded for the degree of M.D., all medical schools possessing the facilities should

establish graduate courses of one year in ophthalmic institutions. In 1912 Jackson addressed an evening session of the Section in Atlantic City, taking as his subject the curriculum leading to the degree of Doctor of Ophthalmology, describing the experiments at Oxford and Liverpool, and his own course at the University of Colorado. This address impelled Samuel D. Risley, of Philadelphia, to deride the postgraduate students "who came for six weeks to a polyclinic to learn refraction and spent their time wandering from clinic to clinic to watch operations; in Europe they got even less out of it because the language was imperfectly understood. Finally there was no way of rating their proficiency." The truth of these charges has been borne out remarkably by the subsequent experience of the American Board of Ophthalmology. These men, who have taken disconnected short courses here and there, have been found to make the poorest showing, and those who have pursued this type of training abroad attain the lowest grades.

There was still no answer to the problem of inducing students to undertake these courses. Why would the average specialist, whose state license permitted him to practice, devote two years to this needless pursuit? And then why should he struggle with a perfectly gratuitous examination?

4. THE JOINT BOARD

The establishment of a state examining board seemed still to be desirable, but no one cared to undertake its organization. The first feeble gesture toward the unique project of an unofficial joint board issuing a certificate to be required for society membership was apparent at the 1913 meeting of the American Ophthalmological Society when John E. Weeks of New York moved to refer to a committee the stiffening of the require-

ments for membership. This action had been urged on behalf of the membership committee by the chairman, George E. de Schweinitz, of Philadelphia. The newly appointed committee was instructed to formulate standards for the proposed Doctorate of Ophthalmology. In his presidential address, Myles Standish, of Boston, had declared that it would be a very diverse degree with the variety of colleges authorized to grant it. It is ironical that he should have been the one to inaugurate a new venture. He was small, competent, as irascible as his Puritan antecedent, but as stand-pat as Plymouth Rock.

It is in the report of this "Committee on Diploma in Ophthalmology" that the primary interest of this article centers—not in what it says, but in what it omits to say. De Schweinitz was chairman of the committee, and the other members were Standish, Risley, Jackson, and Weeks. These men outlined the curriculum that should lead to the proposed degree, and explained the reason for making it Master in Ophthalmology in preference to several other obvious titles. They provided also for a thesis and an examination, but evidently both were to be ranked by the university authorities. The significant thing was the absence of the slightest intimation of a joint examining board. The one step in that direction that can be detected after a painstaking review of the records is a suggestion by de Schweinitz that his committee be combined with that from the Section and from the Academy. This was solely with the purpose in mind of bringing more pressure to bear upon the medical schools for the establishment of graduate courses.

By inference, the project of the joint board must have been conceived during the month elapsing between the meeting of the American Ophthalmological Society at Hot Springs in May, 1914, and

that of the Section in June. As was just stated, Jackson, chairman of the Section committee, was also a member of the American Ophthalmological Society committee, and had signed their report, and four other members of the Section committee, Woods, Wilder, Zentmayer, and Duane, were present at the Hot Springs meeting in May, 1914, and took part in the discussion concerning it. Zentmayer, in particular, was scrupulous to avoid ambiguity in the wording. It seems incredible that they were considering so radical an enterprise.

The report was presented to the Section in June. Jackson observed that the experience of the Royal College of Surgeons of England and that of the Royal College of Physicians of London pointed the way to a practical method of certifying. The members of their conjoint examining board were drawn from 21 schools. Although the board conferred no degree or right to practice, rejected 40 percent of the candidates, and demanded fees of \$210, nevertheless a large proportion of the men entering practice took the examination. Jackson recommended the formation of a board in this country on a similar basis. To complete the arrangements, he advised inviting the coöperation of committees from the American Ophthalmological Society and the Section on Ophthalmology.

It will be observed that there is still no intimation of the provision that the certificate of the Board would be required for membership in the American Ophthalmological Society and the Academy, and for officers and positions on the program of the Section. This seems not to have been proposed until the proceedings of the joint committee were reported in 1915. In that year the American Ophthalmological Society did not meet until July, at New London, Connecticut. This document, which was formulated by the chair-

men of the three committees, was therefore first submitted to the meeting of the Section at San Francisco, under the chairmanship of E. C. Ellett, of Memphis.

One object of this study was to determine how much the formation of the Board was assisted by the optometrist agitation. The opinion of those active at the time is well worded in a letter from John E. Weeks, in which he says: "In regard to the influence of optometrists in bringing about the formation of the American Board for Ophthalmic Examinations, their statement that many ophthalmologists did poor work in refraction could not be denied. Their contention had much to do with causing Connor to propose 'simple refraction for family physicians,' but it was only one of the stimuli that were instrumental in the creation of the examining board, and not an important one."

This ingenious means for persuading oculists to prepare for and take examinations by requiring the certificate of an independent board for society membership is credited to Edward Jackson. This was the culmination of his prolonged relentless warfare on incompetence in the profession, begun at least 30 years previously.

For later consideration are the organization of the Board and its development. That the devoted group associated with Jackson began conducting examinations in 1915 is now history. Up to 1938, in spite of the early complaints by those who resented what they pleased to miscall a "self-appointed tribunal," 55 examinations had been held and 1,440 candidates had been certificated in all parts of the United States and in Canada. In conducting these examinations many of the most distinguished ophthalmologists have been associated with the Board, and leading hospitals have generously provided facilities for them. The certificate has been made a requisite for membership in many sectional and local societies and on hospital staffs. This has had the intended effect of compelling universities and hospitals to formulate courses in preparation for the examination. A characteristic example of the improvement in education has been the introduction, into residencies, of systematized courses of instruction. The most far-reaching and spectacular result of this enterprise, however, has been the adoption of the board method of examination by 11 other specialties and their coordination in the advisory board for medical specialties.

DISCUSSION

DR. GEORGE F. LIBBY, San Diego, California: At Dr. Beach's request, I am glad, after listening to his interesting paper, to speak briefly of the bearing of Colorado on the movement which he has so well described. In 1912, under the auspices of the University of Colorado and with Dr. Edward Jackson's direction, we established in Denver a postgraduate school for advanced teaching in ophthalmology. There were 11 students—one from Pennsylvania, two from the Middle

West, and eight from Denver. Dr. Crisp and I were both students and lecturers in that course, which was of six weeks' duration. Local men and some leading ophthalmologists from other parts of the country lectured and held clinics. In the following year, after a year's reading in ophthalmology under Dr. Jackson's direction, three of us, having passed the examinations, received the degree of Doctor of Ophthalmology at the state university. I am speaking of this because

I believe that the Colorado movement leading to the certification of men who had taken advanced standing in ophthalmology, and also the courses given at that time in the University of Pennsylvania and in the University of Minnesota, leading to the degree of Doctor of Science in Ophthalmology, had a very important bearing on the development of the American Board of Ophthalmology. As I understand the matter, it seemed far better to the men who started the movement to have a national board of examination certify to the attainment of high standing in ophthalmology, rather than to serve that purpose by a doctorate degree; and I think that was the wiser way. I simply wish to express my appreciation of what Dr. Jackson did in Colorado and in our country in helping toward the establishment of this movement. I am thankful that I had a small part in starting the work. As I was at that time 44 years of age, I was told by the younger ophthalmologists that when I stepped up as the first registrant for the course they felt ashamed not to follow. At this time it seems appropriate for me to touch upon what was done in Colorado, and by our Dr. Jackson, to help this movement along.

DR. W. B. LANCASTER, Boston: The Society is grateful to Dr. Beach for this important historical contribution. Perhaps you think it is a simple matter to write such a paper: that all you have to do is to look up the records in the Transactions and find out what was done year

by year! There is a great deal more to it than that. The historian must evaluate what he finds and interpret it for us, and, besides, the records are very meager. They simply say, "it was moved and carried, etc." Take the epoch-making meeting of last night; when the future historian tries to find out the facts, he will simply be confronted with the record, "moved and voted." Nothing will be said of how Horatio held the bridge, who fought on his right hand, and who on his left hand, and what soldiers stood behind him, and how they met the onslaughts of the reactionaries and the die-hards!

Perhaps you think that when the American Board of Ophthalmology was formed matters were all peaceful, but I assure you that was not the case. When the Board first made its appearance many a finger of scorn and ridicule was pointed at it by men in high position. But we were fortunate, in those days, in having for leaders men of vision and of courage, especially of vision, who could see the future while we were still in a fog, and did not see the shining heights above; men who led us on to great achievement, so that now we are proud to have the stone which was rejected by many made the headstone of the corner: Ophthalmology leading all the specialties, from otolaryngology to surgery.

DR. WILLIAM H. CRISP, Denver: In the future we shall say: "There were giants in those days."

CONTRIBUTION TO THE THEORY AND PRACTICE OF TONOMETRY*

II. AN ANALYSIS OF THE WORK OF PROFESSOR S. KALFA WITH THE APPLANATION TONOMETER

JONAS S. FRIEDENWALD, M.D.
Baltimore

In the previous paper¹ a theoretical analysis was undertaken to distinguish the influence of ocular rigidity from that of intraocular pressure on tonometric measurement with the Schiötz tonometer. A method was devised whereby these two components of the tonometric reading could be separately evaluated and their independent variations studied. It is

field; second, to an attempt to relate that work to the study of the Schiötz tonometer.

In his investigations, Professor Kalfa has used the Maklakow tonometer, an instrument of fixed weight with a small plane surface as its base (fig. 1). Measurements are made with this instrument as follows: After 1-percent holocaine anesthesia, a drop of concentrated solu-

Fig. 1 (Friedenwald). Maklakow tonometer (after Lloyd).

much to be regretted that at the time of publication of this study, the writer was unaware of the important contributions which Professor S. Kalfa of Odessa had already made to this subject.^{2, 3, 4, 5, 6, 7} Since much of Kalfa's work may be unfamiliar to the American reader, the present article will be devoted, first, to a review of Kalfa's work in this

tion of bismark brown in water and glycerine is allowed to spread over the cornea. The flat base of the tonometer is now allowed to rest on the cornea for a moment and then a print is made of the area of corneal contact by pressing the tonometer on a piece of paper. The diameter of the print or "tonogram" is measured with calipers. Duplicate measurements are said to agree to 0.1 or 0.2 mm.**

* From the Wilmer Ophthalmological Institute of the Johns Hopkins University and Hospital.

** Applanation tonometry has not been widely used in this country and is generally re-

Kalfa first proved that the act of tonometry with the Maklakow tonometer raises the intraocular pressure. This was accomplished through direct measurements on enucleated eyes of animals and of human beings. The eyes were connected with a manometer through a canula placed in the optic nerve. The intraocular pressure could be brought to any desired level, and the connection to the manometer could be left open or closed. When the tonometer was allowed to rest on the cornea it was regularly found that the intraocular pressure was higher; that is, the area of appplanation was smaller when the connection between the eye and the manometer was closed than when it was open. As further evidence, the author was able to show that if, after tonometry, the Maklakow tonometer is allowed to rest on a normal eye for two minutes, at the end of which time a fresh tonometric measurement is made, one finds the pressure regularly lower on the second tonometry than on the first. This shows that the tonometer, while resting on the eye, raised the intraocular pressure and expressed some intraocular fluid. Finally, Kalfa made use of Maklakow tonometers of different weights and showed that the tonometric measurement regularly yielded a higher reading when a heavier tonometer was used.

From these observations Kalfa concludes that the intraocular pressure is raised by the act of tonometry, and that the true intraocular pressure is somewhat less than that indicated in the tables published by Golowin.* How much the act of tonometry changes the intraocular pres-

garded as less accurate than indentation tonometry. The relative merits of the two procedures are, however, irrelevant to the present discussion.

* Tables based on the law of Fick and Maklakow, see below.

sure depends among other things on the elasticity of the eyeball. Since tonometers of different weights produce different changes in intraocular pressure, a comparison of readings made with tonometers of different weights on the same eye can yield information concerning the elasticity of the eyeball. Filatow had previously prepared a set of Maklakow tonometers weighing respectively 5.5, 7.5, 10, and 15 grams, and these were placed at the disposal of Kalfa. In using this set of tonometers, the latter measured first with the lightest instrument and then with successively heavier instruments. On normal eyes the successive measurements invariably yielded successively higher pressure readings when the pressure was determined with the Golowin tables. The results for a single case or the average results for a group of cases may be charted as shown in figure 2, the pressure as ordinate, the tonometer weight as abscissa. The author denotes such a graph as an "Elastometric curve." Such curves obtained on normal people usually approximated straight lines. The slope of the curve, or more specifically the rise in pressure from the 5.5 to the 15 gram reading was used as a measure of rigidity. This may be designated "Elastometric Rise" or E. R. Evidently of two eyes with the same intraocular pressure the one with the greatest E. R. is the more rigid.

In 100 normal eyes the average E. R. was 9.9 mm. Hg, with 7.1 and 12.1 as the lower and upper limits. The E. R. increases with age, the greatest changes being before the age of 20. In progressive myopia the E. R. is noticeably less. In untreated glaucoma the E. R. is greater than normal and the elastometric curves are often irregular with steps or peaks, heavier weights sometimes yielding lower pressures than previously used lighter weights. Most irregular curves are ob-

tained in treated glaucoma. Kalfa has devoted special attention to the irregularities in the elastometric curves in glaucoma, and has used these to study the vasomotor reflex regulation of intraocular pressure, a subject of great interest which does not, however, concern us here.

The simplicity of the approach to this problem that Kalfa has achieved with the applanation tonometer stands in

in elasticity introduce errors in pressure readings in ordinary tonometry, so variations in pressure introduce errors in rigidity readings, for the tonometric reading that is the basis for determination of either pressure or rigidity is actually determined jointly by these two features.

In order to separate rigorously the pressure and rigidity factors in the tonometric measurement, an analysis similar

Fig. 2 (Friedenwald). Elastometric curves of Kalfa (see Ref. 5, p. 277). I, 7-year-old boy; II, average of 14 patients aged 10-14 years; III, average of 10 patients aged 15-19 years; IV, average of 9 patients aged 20-25 years; V, average of 10 patients aged 30-55 years.

marked contrast with the complex treatment that a similar analysis of the measurements with the Schiötz tonometer required. The validity of both methods is supported by the widespread agreement in clinical observations achieved independently. Without by any means disparaging the simplicity of Kalfa's solution, it may be pointed out that this simplicity has been reached through the neglect of one feature in the elastic reactions of the eyeball. It is evident that if the pressure in two eyes is equal, the eye that has the steeper elastometric curve is the more rigid, but the analysis of Kalfa provides no means of comparison between eyes with unequal pressures. Just as variations

to that which was undertaken previously in relation to the Schiötz tonometer is required. When the tonometer rests on the cornea it deforms the cornea and displaces fluid equal to the volume of the deformation. This displaced fluid is accommodated within the ocular cavity by a stretching of the ocular coats and by a displacement of some blood from the intraocular vessels. Depending on the resistance that is offered to this displacement, a greater or smaller rise in intraocular pressure will occur. In the previous paper it was shown that for any given eye the same volume displacement always produced the same percentage of change in pressure. Stated mathematically:

Log $P_2 - \text{Log } P_1 = K(V_2 - V_1) \dots (1)$
Where K is a constant characteristic of the eye measured, hence K may be taken as a measure of ocular rigidity.

designated the coefficient of rigidity. It is independent of the particular range of pressure over which the determination is made.

In order to determine K we must know the values of P and of V ; that is, the ac-

Owing to the complex form of the corneal indentation produced by the

TABLE 1

RELATION OF DISPLACED VOLUME AND INTRAOCULAR PRESSURE CORRESPONDING TO DIFFERENT DIAMETERS OF APPLANATION AS MEASURED WITH THE MAKHLAKOW TONOMETER

Diameter of Applanation mm.	Volume Displaced mm. ³	Pressure in mm. Hg with Various Tonometer Weights			
		5.5	7.5	10	15
2.0	0.1	128	175	230	350
2.5	0.2	64	88	115	175

8.5	38.0	7.2	9.8	13.1	19.6

tual intraocular pressure and the volume of the corneal indentation corresponding to tonometric measurements with different weights. When these paired values of P and V are known, they can be charted on a scale that is linear with respect to volume and logarithmic with respect to pressure. Such points fall on straight lines and the slope of the line drawn through them is a measure of K . The value of K , so determined, has been

Schiötz tonometer, considerable complexity was encountered in determining what volume of indentation corresponds to given tonometer readings. In respect to the applanation tonometer, no such complexity exists, for the volume of the displaced fluid may be assumed to correspond to that of a segment of a sphere having the tonogram for base and the undistorted cornea for dome.* Table 1 gives the volume calculated to correspond

* These simple assumptions yield volume estimates that are only approximately correct. Variations in corneal curvature and the presence or absence of corneal astigmatism introduce errors that could be allowed for only by very laborious calculations. Kalfa has pointed out that during applanation the corneal lamellae probably slide over one another so that the area of the tonogram may be larger than the area of the base of the flattened area on the inner surface of the cornea. Furthermore, capillary attraction may cause some enlargement of the tonogram, and any rocking or slipping of the tonometer or the cornea would have a similar effect. There appears to be no direct method of allowing for these errors. On the whole they should lead to an underestimate of intraocular pressure and an overestimate of displaced volume.

The formula for calculating the volume of a segment of a sphere is: $V = \pi a^2(r - \frac{a}{3})$ in which r is the radius of curvature of the sphere (in this case 7.8 mm., the average radius of curvature of the cornea), and a is the altitude of the segment. The latter is given by the formula: $a = r - \sqrt{r^2 - R^2}$ in which R is the radius of the base of the segment of the sphere; that is, the radius of the tonogram.

to different diameters of the tonogram, and also the intraocular pressure calculated by the formula of Fick and Maklakow.**

The data of table 1 may now be combined graphically in the chart shown in figure 3, which is analogous to the nomo-

displaced fluid, corresponding to a given tonometric reading. If readings are made with the four different tonometers and are plotted on this chart, they should, if our theory is correct, fall approximately on a straight line. The slope of such a line is the coefficient of rigidity of the eye

Fig. 3 (Friedenwald). Chart for the determination of ocular rigidity from tonometric readings with the applanation tonometer.

gram for determination of ocular rigidity and pressure with the Schiötz tonometer published in the previous paper. The four curves correspond to applanation tonometers weighing respectively 5.5, 7.5, 10, and 15 grams. The ordinates of points on these curves are proportional to the logarithm of the pressure, the abscissas are proportional to the volume of the

measured. A set of sloping lines for graphic comparison, and the numerical values of their slopes, is included in the upper portion of the chart.

In figure 4 are charted the data of Kalfa that are given in the first and last elastometric curves of figure 2 above. The slopes of these curves are respectively 0.011 and 0.021. The five elasto-

** This formula is based on the necessary equality of the upward force of intraocular pressure operating over the area of applanation and the downward force of the weight of the tonometer: $W = P \times A$. The pressure in grams per square millimeter is readily transformed into millimeters of mercury as given in the table. This portion of the table is identical with that of Golowin referred to above.

Fig. 4 (Friedenwald). Kalfa's data, from figure 2, charted for determinations of ocular rigidity.

metric curves of figure 2 were presented by Kalfa to show the variation of these curves for different age groups of normal persons. In table 2 the values of rigidity coefficients computed from these five curves are given, and compared with the average rigidity coefficients of corresponding groups as determined with the Schiötz tonometer, and reported previously. Considering the number of simpli-

fying assumptions that were introduced into both calculations the agreement between these two independent sets of measurements is remarkable.

It is evident from the above that the chart given in figure 3 may be used with Kalfa's elastometric diagram as a pair of mutually complementary dictionaries for the translation of values of rigidity coefficient into corresponding values of

TABLE 2
RELATION OF RIGIDITY TO AGE

Kalfa			Friedenwald		
Age	Number of Cases	Coefficient of Rigidity	Age	Number of Cases	Coefficient of Rigidity
7	1	.011			
10-14	14	.011			
15-19	10	.018	15-30	135	.021
20-25	9	.019	30-50	182	.021
30-55	10	.021	50-60	102	.022
			Over 60	81	.029

elastometric rise. This translation is reduced to a single chart in figure 5 in which it is seen that small values of elastometric rise (E. R.) correspond to fairly stable values of rigidity coefficient, irrespective of the pressure level at which the measurement was recorded, but that larger values of E. R. correspond to values of rigidity

ing for the intraocular pressure independent of the ocular rigidity. A similar and much simpler computation may be made for the applanation tonometer as follows: Let us suppose that tonometric measurements have been made on a given eye with the four different Maklakow tonometers and that the results of these

Fig. 5 (Friedenwald). Relation of elastometric rise of Kalfa (E. R.) to rigidity coefficient of Friedenwald is shown to vary with intraocular pressure.

which vary markedly with pressure. The pressure indicated is that determined with the lightest tonometer (5.5 gm.). Applying this chart to the data given by Kalfa for the maximum range of variation of E. R. (from 1.8 to 27.9) the corresponding range of variation of rigidity coefficient is from 0.002 to 0.100, figures which again correspond to the findings with the Schiötz tonometer.

In respect to the Schiötz tonometer, a method was worked out to obtain a read-

measurements have been charted as four points on the nomogram (fig. 6). A straight line is drawn as nearly as possible through these four points. The slope of this line, as before, is a measure of the ocular rigidity. If we imagine ourselves passing down this line from upper right to lower left, we should be passing through a series of points corresponding to measurements with lighter and lighter tonometers. The point (P) where the line crosses the vertical axis corresponds

to the measurement with a tonometer of infinitesimally small weight and hence, to the true intraocular pressure undisturbed by the act of tonometry.

Applying this method of computation to Kalfa's data for normal eyes, we reach an estimate for the average normal intra-

ocular pressure of 15 mm. Hg. This figure is in marked disagreement with the results obtained with the Schiötz tonometer from which the average normal intraocular pressure was computed to be 25 mm. Hg. This discrepancy is far too large to be accidental. As indicated above, a discrepancy of this sort was to be expected owing to the fact that the diameter of the tonogram is enlarged by a variety of factors. A simple calculation shows that if the radius of the tonogram as measured were regularly reduced by 0.5

Fig. 6 (Friedenwald). Method of using the rigidity chart to determine intraocular pressure from readings with the applanation tonometer.

ocular pressure of 15 mm. Hg. This figure is in marked disagreement with the results obtained with the Schiötz tonometer from which the average normal intraocular pressure was computed to be 25 mm. Hg. This discrepancy is far too large to be accidental. As indicated above, a discrepancy of this sort was to be expected owing to the fact that the diameter of the tonogram is enlarged by a variety of factors. A simple calculation shows that if the radius of the tonogram as measured were regularly reduced by 0.5

the two instruments in the measurement of rigidity.

In summary, it has been possible to apply to Kalfa's elastometric measurements with the applanation tonometer the same type of analysis that the writer has in a previous publication applied to data obtained with the Schiötz tonometer. The agreement of the results furnishes a most satisfactory check on the correctness of this analysis. The elastometric rise that Kalfa has chosen as a measure of ocular rigidity is shown to

be closely connected with the coefficient of ocular rigidity as designated by the writer. The relation between the two is not linear but, in general, these two measures tend to increase or decrease together. The greatest discrepancies between these two measures is to be found in cases of low intraocular pressure and high ocular rigidity. In this group of cases the rigidity measure of Kalfa gives relatively smaller measurements than that of the writer. It is perhaps on this ac-

count that Kalfa failed to note that the ocular rigidity of persons with high myopia was greater than that of persons with low myopia, and also that there is a group of hyperrigid cases among otherwise normal old persons.

The number of cases that fall into this region of lesser agreement is, however, quite small. The results obtained by the two methods are thus capable of confirming and supporting each other.

SUBJECTIVE STUDY OF VISUAL ABERRATIONS*

EDWARD JACKSON, M.D.

Denver

In the foreword to a recent edition of Sir Isaac Newton's "Optics," Einstein wrote: "Fortunate Newton, happy childhood of science! He who has time and tranquillity can, by reading this book, live again the wonderful events which the great Newton experienced in his young days." But the "childhood of science" has not passed; perhaps it is only beginning; and we, by experiment, may also read the open book of nature. Newton's "Optics" explained the rainbow, and laid a broad foundation for others to build upon. But the work of Oersted, Faraday, Kelvin, Clerk-Maxwell, and recent astronomers has pushed aside Newton's theory of gravitation, making place for the "relativity" theory of Einstein. Some of the oldest impressions and observations of vision still remain to be understood and explained.

The earliest representations of the stars and sun closely resemble the representations of them made today. Yet there has been no clear understanding of them. Helmholtz gave a representation of the appearance of "monochromatic aberrations" of his own eyes, but offered no explanation of their significance. Why do we see a star as a point of light?—not a mathematical point, but a bright object, extending irregularly in different directions. A telescope reveals a fixed star as a mathematical point, and a planet as a small round disc, without any irregular extensions. These are the true images formed by a perfect lens or perfect lens systems. What we see are the images formed by imperfect human eyes; and the

irregular projections are the effects of the monochromatic aberrations of imperfect eyes, no two of them exactly alike.

These star images may easily be studied by simple experiments, with very simple apparatus. When looking at a star in the evening, close first one eye and then the other: it will be noted that the images in the two eyes differ. The principal projections of light for one differ from those of the other. They extend in different directions, and branch differently. The use of lenses before the eye changes these projections and they vary with the size of the pupil. They exist through optical defects of the eye, and any change in the refractive conditions alters them.

We see the stars through relatively dilated pupils. It is easy, by covering some part of the pupil, to observe just what part of the image is formed by light passing through that part of the pupil. Looking at night at a star, or at a distant street light, the edge of a card may be brought before the pupil. As the edge of the card begins to cover a part of the pupil, a part of the image of the light disappears. The image that remains is formed by the part of the pupil still uncovered. If covering the bottom of the pupil removes the bottom of the image, the part covered is myopic. If covering the bottom of the pupil obliterates the upper part of the image, the aberration of that part of the pupil is hyperopic. If a corner of the card is thrust before the pupil, the part of the image lost will belong to that quadrant of it. In this way each part of the image can be connected with the part of the pupil causing it. When looking at a star through a circular opening, the periphery of the pupil

* Presented at the Seventy-fourth Annual Meeting of the American Ophthalmological Society at San Francisco, California, June 9, 1938.

will be excluded, making the opening smaller. When the opening is small enough, the aberration of the periphery of the pupil is excluded; and a star may become a point of light, as it appears when observed through a telescope.

Multiple crescent moons are caused by aberrations of the eyes. With a card to cover first one part of the pupil and then another, we can connect each image with the part of the pupil causing it. When a patient complains that he "sees too many moons," a demonstration of how such images are caused may relieve his anxiety, and create a confidence that the physician understands his case and can help him. By such subjective study of his own eyes, the ophthalmologist may watch the progress of changes in them, especially refractive changes.

It is possible to study your own refraction by autoskiagraphy,* using one eye to examine the refraction of the other. But the use of the subjective method, by means of a bright star, a distant street lamp, or an automobile headlight as the source of light, is generally more available and more convenient. This method can be taught to patients who are curious or morbid with reference to their own visual defects.

Representations of the sun, a disc of light (too intense to be looked at) with a region of brilliant illumination about it, and rays emanating from it in all directions, are composite images, based on general experience, going back to the early development of the race, that can be confirmed by the experience of each of us. So far as appears, there has been no careful study made of the physical basis of the impressions so expressed. No intelligent study of this phenomenon was possible until, within the last century, we learned the minute anatomy of

the eye and the mechanism of visual perceptions. Our subjective studies may further our understanding of visual optics, and may throw some light on the essential basis of vision.

What is now understood of the radiations from the sun and the luminous projections of its corona, as photographed at times of total eclipse, might lead us to explain the radiations we have seen as a general physical phenomenon, apart from vision. But experiment indicates that it occurs not in the sun or our atmosphere, but only in our eyes—a phenomenon especially suited for individual subjective study.

This appearance may be observed by the old experiment of looking at the reflection of the sun in a globule of mercury with a background of black velvet. This gives us a point of bright light at the center, with a background so dark that the single rays may be seen diverging in all directions. Such an image can also be seen at night by looking at a bright electric light far enough away to appear as a point. It is now most frequently seen in the reflections of the sun from the curved, polished surfaces of an automobile. It may best be studied by looking at the sun, or its reflection, through a very small opening in a metal plate, keeping the retina dark-adapted by the exclusion of other light.

When studied through a small opening, which may be shifted in front of different parts of the pupil, it is found that the divergent rays are reflections from the substance of the crystalline lens, very near to its anterior pole. The only structures that can give such reflections from that part of the eye are the surfaces of the lens fibers converging to their anterior attachments. The minute anatomy of these converging fibers has not been studied with reference to this particular optical effect; but for the glass membrane

* Jackson, E. *Ophth. Rev.*, 1897, v. 16, p. 227.

that covers them, or the particular lens Y to which they are attached, to cause such radiating lines is most improbable. The number of these fibers and the arrangement of their broader sides fit them to such reflections of the light falling upon them.

It must be remembered that in an eye with clear media, the rays we see are not like pencils of light passing through a smoke chamber. They are produced only by the light that has fallen on the sensitive layers, the percipient elements, of the retina. Light is invisible in the transparent media of the eye, just as it is when passing through the transparent atmosphere. The red rays of sunset are not visible in clear air. They are manifest only as they fall on clouds, smoke, or other visible objects. The radiating lines seen in the eye are the impress of light falling on radiating lines of retinal percipient elements. They are visible only through parts of the retina that are situated so as to receive them, and sensitive enough to be affected by them. They generally extend for 10 or 20 degrees from the fixation point, and sometimes twice that distance. The extent of the area of the radiating lines is dependent on the brightness of the source of light and the retinal light adaptation. They are not seen in the area of the physiologic blind spot. But this cannot be sharply outlined, because that requires light adaptation, whereas the perception of the radiating lines requires dark adaptation.

Another optical phenomenon allied to that just described is the radiations seen diverging from bright lights; these are caused by the reflections of light from the moist edges of the eyelids. This manifestation also has not received the attention that its frequency entitles it to receive. These bands of light, extending upward or downward, or both upward and downward, may be seen on gazing at any

bright source of light when the pupil is wide enough to extend to the lid margins. Such bands of light have doubtless been observed by every one, but they have been regarded as only a kind of glare, which may be dispelled, changing the relation of the lids to the direction of the source of light; opening the eyes widely, or looking in another direction, or closing the eyes. The direction of the band of light is perpendicular to the direction of the part of the lid margin from which the light is reflected. If these reflections come from near the center of the lids, where the margins are parallel, one coming from the upper lid will go directly down, and one from the lower lid will point directly up. If the reflections come from the lid margins near either canthus, they take correspondingly oblique directions. When the lids are almost closed, their margins are so nearly parallel to the direction of the light rays that can reach them that these reflections are not noticed. When the eyes face a very strong light, the pupils contract, so that the reflections from the lid margins do not reach the pupil. When the pupil is dilated, the light reflected from either or both of the lid margins is an important part of the glare that patients complain of as the effect of the use of mydriatics. When we look at the reflections of the sun from the curved surfaces of an automobile, the reflections from the lid margins may be seen along with the radiating lines of the reflections from the anterior pole of the lens. The breadth and direction of the lid reflections distinguish them from the radiating lines caused by the lens.

It is probable that the reflections of strong light from the lid margins and the crystalline lens to the interior of the eye have an important influence on the metabolism of the retina. They diminish the excessive brightness of images formed on one part of the retina, and distribute

a part of the light to all portions of the pigment layer of the retina, without preventing the perception of retinal images useful for vision. They should be considered in relation to retinal nutrition, or light and dark adaptation.

We cannot assume that only the light coming from a strong visible source, like the sun, is reflected in that way. The light from every source, including the diffuse light of the sky on this same reflecting surface, is reflected in the same way. With feebler sources of light, however, the radiating lines in which they are reflected would not be perceived by the retina, constantly adapted to the total light falling on it. In this way a large part of the light entering the pupil is uniformly diffused over the pigment layer of the retina.

From the enormous influence on plant life of light falling on the chlorophyl and allied substances in the leaves we can best conceive the importance of this diffuse light constantly falling on the pigment layer of the retina. The loss of visual acuity, when the percipient layer of the retina is separated from the pigment layer by detachment of the retina, gives us an idea of the vital importance of the normal retinal pigment in the mechanism of vision. The same lesson is enforced by the defective vision always found with albinism, which impairs the choroidal and retinal pigmentation of the eyes. The physiology of vision is so complex and unexplored a subject that we need every possible assistance, by the subjective

study of our own vision, to help us assign the relative importance of measures available for ocular therapeutics or preventive medicine.

The subjective study of the reflection of light from the crystalline lens may also be of diagnostic importance. Pursuing the line of entoptic investigation described by Donders, studies of the writer's own eyes have revealed unsuspected opacities in both crystalline lenses near the anterior poles. Through an aperture 0.5 mm. in diameter the opacities were observed to be always of the same shape, they were seen very close to the anterior pole of the lens, and were brownish-gray in color. In this case, these have probably been left by a long-completed process. But lesions detected by this method of examination might be watched through their early active changes, when they would reveal something of their nature and causation. The lens substance, highly specialized and generally remaining transparent for many years, is a tissue about which we know little, and which we should study in order to be able to prevent cataract formation.

Subjective study of phenomena in the borderland between vision, neurology, and philosophy may also be a corrective, for there is a tendency for examinations of patients to become habitual, routine, and unproductive. It may help us to learn to retard the development of senile changes, and to avoid professional failures and disappointments.

Republic Building.

DISCUSSION

DR. W. B. LANCASTER, Boston: The conventional idea of a lens pictures the rays of light from a point P falling on the lens and then all of them focused to a point P' on the other side of the lens. This is not even approximately true. The

rays falling on the lens are correctly represented as all emanating from a point P, but after refraction these rays do not all go to the point P'. If we take the central ray and the two adjoining it (an infinitely small beam), these do meet at

a point, but none of the peripheral rays are refracted to this same point. The result is that we have a congeries of rays crossing one another, not all at one point, but at many points. Much the same is true of the eye. The rays from a point after refraction by the cornea and the lens do not meet at a point. If the pathway of the rays is studied, it is found that the rays are grouped together so that if cross sections are made at various points by letting the rays fall on a screen and observing the images when the screen is at different distances, it is found that, at a point slightly posterior to the schematic focus, the rays are well concentrated at the center, but are surrounded by scattering rays like whiskers, which Dr. Jackson spoke of as radiating sometimes 20 degrees or more from the center. If instead of a bright light as a source a black spot on a white card is chosen, these whiskers are invisible—too faint to be seen—and we obtain a pretty accurate focus in the center.

If the screen was in front of the schematic focus, then the grouping of the rays would be most concentrated, not in the center but around the circumference, the light being fainter in the center (negative aberration). That does not give a good image.

What the accommodation has to do is to pick out the place somewhere between the anterior and the posterior part of the focal line, as it has been called, where the image is the best for seeing, and that is what the eye is doing all the time, making the best use it can of the muddle of rays by picking out for the retina that cross-section of the beam which, under the conditions, makes the most serviceable image. If you paralyze the accommodation, the eye is unable to select the best place. Moreover, with the enlarged pupil, numerous extra rays are admitted which complicate the picture and compel

the eye to select a different point for the best focus. Dr. Crisp made a very keen observation when he stated that in this mixture of rays the eye has a habit of selecting one place which suits it the best, and when, by dilating the pupil, we introduce other rays at the periphery of the pupil, the eye still is able to adhere to its original preferred point, but I do not think we ought to count on that. The eye may do that in some cases, but if we want to learn what the eye does, we must examine it under the conditions in which it is really working, and not limit these at any rate to the conditions under cycloplegia, because then the aberrations are quite different and the eye must make a different adjustment.

DR. EDWARD JACKSON, closing: This subject is new to me, and is probably new to most of the members of the Society, but it seems to be a subject of importance. These aberrations of light coming into the eye, which I have described, are common to all eyes. I have tested many persons on seeing radiating lines about the reflections from an automobile. You cannot drive a block in any city on a clear day without encountering them; and these reflections from the sun are bright enough to be seen by our ordinary light-adapted eyes. I have studied them in my own eyes preferably with an opaque disc, with three small holes drilled into it: one, 1 mm. in diameter; one, 0.5 mm. in diameter; and one, 0.25 mm. in diameter. I thus study the divergence of the rays from the point of light, when everything else is cut out by a black diaphragm. The 0.5-mm. diameter opening in this metal disc is, perhaps, the best one to work with. The 0.25-mm. diameter is somewhat small.

By this manner of examining my own eyes I have discovered a defect in each lens near the anterior pole. I have vision such as is ordinarily recorded 1.3 with

my correcting glasses—as good as I had when I was 30 years old, but I discovered a point of partial opacity. There is a brown partial opacity near the anterior pole of each lens. I have had my eyes examined with a corneal microscope by a colleague who could see the opacity in each lens. That is a clinical matter. I do not believe the opacity in my lenses is of much practical importance, but we can learn something about opacities of the

lens by studying them on ourselves with a brilliant point of light, reflected from some surface. By shutting off the mass of light in general that is received on the retina from an object, we get a dark field in which are the radiating lines caused by reflection from the anterior pole of the lens near the center of the pupil. The radiating lines are best seen when the light is admitted as near as possible to the anterior pole of the lens.

ERYTHEMA NODOSUM WITH NODULES IN THE CONJUNCTIVAE

A CASE REPORT

LOUIS S. GREENE, M.D., AND MATTHEW WHITE PERRY, M.D.
Washington, D.C.

We have observed a patient with erythema nodosum complicated by nodular lesions in the conjunctiva of each eye. A search of the medical literature reveals few references to such an occurrence and, in view of this, it is thought worth while to report the case.

CASE REPORT

Mrs. E. E., an American housewife, aged 54 years, was first seen by one of us (M. W. P.) in September, 1935. At that time she complained of exhaustion. A thorough study revealed little except hypertrophic changes in the tonsils and injection of the pillars. Examination of the various systems was negative. Routine examination of the blood and urine revealed no abnormal findings. The blood Wassermann and Kahn tests were negative. A tonsillectomy was performed, following which she improved symptomatically.

Two months later the patient presented herself complaining of an inflamed condition of both eyes, of one week's duration. There was no discomfort connected with this condition and there was no pain produced by motion of the eyeballs in any

direction. Though she had quickly recovered from the tonsillectomy, she stated that the right side of her throat had been sore for a few days. She also complained of some soreness in both knees. Examination of the eyes at that time (L. S. G.) yielded the following results: Vision in each eye, with myopic correction was 6/6. The corneae and irides were normal. The pupillary reactions and muscular balance were normal and the media were clear. On external examination there was no swelling nor thickening of the eyelids, and the tarsal conjunctivae were normal. Situated over the insertion of the four recti muscles in each eye there was a triangular, cherry-red area of hyperemic conjunctiva with its base at the limbus, spreading out fan-shaped as far back as the equator of the eyeballs. Under the slitlamp these areas presented a superficial wide-meshed network of vessels of a dark cherry-red hue, confined solely to the bulbar conjunctiva (fig. 1). The areas were freely movable over the sclerae, which were both normal in color and texture. Located at about the center of each of these areas were from two to four nodes the size of a small pinhead. Under high

power each node appeared to be situated in a slightly sanguineous fluid through which could be seen a network of small vessels surrounding each node. One or two of the nodes showed slight staining by fluorescein. An intradermal tuberculin test was negative.

nodules and the erythema nodosum gradually disappeared, becoming completely absent approximately four weeks after their appearance. Fever coincidentally disappeared.

Eight weeks after the onset of the illness the patient had completely recovered.

Fig. 1 (Greene and Perry). Erythema nodosum with nodules in the conjunctiva.

Five days later, for the first time, the patient was found to have slight elevation of her temperature. She complained of pains in the joints and general malaise. On examination the pharynx was diffusely reddened. There was slight swelling and pain on motion of the ankle, wrist, and knee joints. Over the extensor surfaces of the arms and legs below the elbows and knees were scattered the typical reddened nodules of erythema nodosum. She was given sodium salicylate (45 gr. daily) and advised to remain in bed. Hot throat gargles were prescribed.

One week later the arthralgia had improved. There was little change in the erythema nodosum and no change in the ocular nodules. For the next three weeks she continued to have low-grade joint pains and slight malaise. Her temperature showed daily elevations as high as 100°F.

Over this three-week period the ocular

She no longer complained of the joint pains and her temperature had remained normal. There had been no recurrence of the nodules in the skin or eyes. Throughout this entire time she had continued to take sodium salicylate.

She has been seen at intervals to date (July 1, 1938) and she has had no recurrence of the disease.

COMMENT

Reports of ocular nodules appearing concomitant with erythema nodosum have but rarely appeared in the foreign literature, and in so far as we can determine are absent from the American literature. Reis,¹ in 1906, and more recently Schieck,² have commented on the occasional appearance of a triangular nodular area in the eyes of persons with erythema nodosum. Beaudonnett,³ Weltistscheff,⁴ Rotth,⁵ Rameev,⁶ and Krachmalnikov⁷ have each described one or more cases

of erythema nodosum with hyperemic and movable ocular nodules which appeared and disappeared together with the skin nodules. The similarity in these independently described cases is striking. Feigenbaum⁸ has also reported four cases of erythema nodosum with ocular involvement, the author terming the unusual complication "metastatic furuncular episcleritis." The patient in one of these, a middle-aged person, in addition to the skin disease and a "florid episclerotic nodule" in the left eye, suffered with acute inflammatory disease of the joints. Involvement of the joints appeared in this patient together with that of the skin and eyes. All symptoms completely disappeared following the administration of salicylates. Carstein⁹ has also reported a similar case, the patient being a middle-aged person who, in addition to erythema nodosum and "elevated reddened patches in the region of the limbus of both eyes,"

developed acute polyarthritis with the onset of the disease. These two cases seem nearly similar to the one described by us.

The nature of the ocular nodules, seen in these cases and in the one observed by us, is a question of considerable conjecture. Their physical characteristics seem not dissimilar from the characteristics of skin nodules. Both are of purplish-red color and movable. Their simultaneous appearance and disappearance seem significant. It seems reasonable to suppose, therefore, that the mode of production of the nodules in each location is of a related, if not identical, nature.

SUMMARY

A case of erythema nodosum with nodules in the conjunctiva is reported.
1710 Rhode Island Avenue.
800 Sixteenth Street, N.W.

SHALL WE USE CYCLOPLEGICS?*

WILLIAM H. CRISP, M.D.

Denver

Among ophthalmic physicians there has been a somewhat general agreement as to the desirability of using cycloplegia in the majority of refractive examinations. Some optometrists condemn cycloplegia, and present to the layman a dark picture of the dangers that accompany the instillation of cycloplegics. That such propaganda is purely selfish in character can hardly be doubted. Moreover, if the law were modified to allow optometrists to use cycloplegics, they would be the first to announce the advantages to be gained to their customers or patients, and would promptly avail themselves of such legal sanction.

There are a few ophthalmologists who, while they do not condemn the use of cycloplegia in refractive work, nevertheless consider the general use of cycloplegics unnecessary for even objectionable.

One may readily acknowledge that it is not absolutely necessary to resort to cycloplegia in every refractive examination, even in fairly young persons, although very few ophthalmologists venture to deny the necessity of employing cycloplegia in children of preschool age. The question is, would a general disposition to give up the use of cycloplegics in adults serve or disserve the public interest?

I have repeatedly asserted that no one can be regarded as an expert refractionist who could not make an approximately accurate measurement of the refractive error without cycloplegia in most of his patients. It is to be regretted that many medical refractionists do not make a careful analysis of the patient's refraction

until the ciliary muscle has been paralyzed, and then base their measurements almost entirely upon the retinoscopic findings, supplementing these findings, at best, with a hurried and inadequate check-up of the corrected vision at the trial case.

Let us consider the three types of refractive error, two or all of which may, of course, be present in the same patient. Taking first myopia, it has often been stated, and with some degree of accuracy, that myopic errors can usually be estimated correctly without the aid of cycloplegia. This is perhaps truer of high amounts of myopia than of low amounts.

It is an important principle of refraction work that an eye that exhibits a small amount of error is more likely to suffer from eyestrain than one with a high error. It is too generally assumed that low as well as high myopic errors do not cause eyestrain. But I have repeatedly found symptoms of eyestrain in cases in which both eyes showed very low myopic errors, even when unaccompanied by astigmatism. The reason for this may be found in the tendency of patients with a moderate amount of myopia to attempt to improve vision by habitually squeezing the eyelids together. Such a habit may give rise to important mistakes or to uncertainty in the measurement of the refractive error. The use of cycloplegia tends to overcome this habit and so affords greater accuracy in making the refractive measurement. It should be remembered, too, that myopic eyes are often benefited by the rest that cycloplegia affords.

A further objection to the indiscriminate omission of cycloplegia in myopia consists in the fact that many patients

* Presented at the Seventy-fourth Annual Meeting of the American Ophthalmological Society at San Francisco, California, June 9, 1938.

have either an inequality of refractive error as between the two eyes or a combination of astigmatism with myopia, or both conditions. Any one of these combinations favors the development of a habit of straining the eyes or eyelids in an attempt to secure better vision, and in this way defeating the efforts of the examiner to discover the exact refractive error.

In regard to hyperopia, there is less tendency to deny the advantage or necessity of employing cycloplegia. I do not feel that the distinction is an entirely logical one or is altogether borne out by experience. In the majority of hyperopic cases a careful preliminary test without the aid of cycloplegia discloses either approximately the same amount of hyperopia as is subsequently determined with cycloplegia or within one fourth of a diopter of that amount of hyperopia. This is not to be understood as stating that I do not find significant differences under cycloplegia; such differences often appear in the form of altered measurement of the amount or axis of astigmatism. On the other hand, a fair number of cases of myopia will display one fourth of a diopter less myopia under cycloplegia than without it.

True, there are a few cases of hyperopia in which the error found under cycloplegia is much greater than that found without cycloplegia. These are the patients in whom the problem presents itself as to whether to give the full correction for the error found under cycloplegia; in other words, whether to face the possibility of having to climb down or that of climbing up from the amount of hyperopic prescription at first given.

My statement as to the large proportion of cases of hyperopia in which I find almost or quite as great an amount of hyperopia before as after the use of cycloplegia may arouse question or criti-

cism. To obtain such results it is necessary to make thorough use of the fogging method and of the astigmatic dials or cross-cylinder tests, or of both; and, above all, to supplement the usual fogging technique with final fogging of both eyes simultaneously. It is well to remember that the patient will use his prescription for both eyes together instead of singly—a most important reason for ascertaining the amount of hyperopia as disclosed by fogging both eyes simultaneously.

Especially when we come to the measurement of astigmatism are we likely to find important differences between the correction without and that determined with cycloplegia. Without cycloplegia, careful estimation of strength and axis at the trial case may frequently lack definiteness or accuracy. It may be asserted that in such cases the examination without cycloplegia is sometimes more accurate than that made under cycloplegia. My own experience has occasionally, but by no means usually, borne out such an impression. In spite of the fact that the astigmatic error very often, or even usually, varies in different parts of the same pupil, there is good reason to suppose that for perfect vision the brain commonly selects a limited area of the pupil, whether or not the pupil is dilated. I believe that in most eyes this selected area remains approximately or precisely the same under all the varying diameters of the pupil, including the temporary marked dilatation under cycloplegia. The chief advantage of cycloplegia thus lies in relaxation of the ciliary muscle, rather than in the opportunity afforded for exact retinoscopy.

There are a few patients in whom the loss of time incident to the use of cycloplegia is an important factor, or in whom the prejudice against cycloplegia is insurmountable. The inconvenience is usually less than was anticipated, especially

as regards homatropine, and particularly if eserine is used to counteract the ciliary relaxation. Now and then, in cases in which it is found necessary to use hyoscine or atropine, I instruct the optician to supply a temporary supplemental pair of +2.50 diopter spherical lenses for close work.

In some adults who show special resistance to the use of cycloplegia, one may try the effect of using a 2-percent-cocaine solution a half hour before beginning the test, instructing the patient to keep his eyes closed during the interval. Many of our difficulties arise from habitual pressure by the eyelids in the patient's attempt to obtain clearer vision. In such cases a mild solution of cocaine is valuable for the increased palpebral opening which it produces, and for the associated relaxation of eyelid pressure. With Beach's combination of Benzedrine (amphetamine sulfate) solution with a reduced quantity of homatropine, my experience has been somewhat inconclusive.*

The argument as to the toxic effect of cycloplegics has very little weight. In this age of the use of the tonometer for measuring intraocular tension, no one should fall into the error of administering numerous doses of a cycloplegic to a patient with incipient glaucoma. In very doubtful incipient cases of glaucoma it may be an advantage to cause a rise of tension under homatropine, for in this way the diagnosis may be rendered more certain and the indication for therapeutic measures may be more definite.

As to the occasional case in which there is sensitiveness to homatropine, or even to other cycloplegics, this may be managed by observance of the rule to which I have called attention elsewhere; namely, that the cycloplegic should be administered shortly after the ingestion of a

meal. If this rule has not been observed, the tendency to nausea, unsteadiness, or other related symptoms may often be very readily overcome by having the patient take food immediately.

Except in cases in which we must face the alternative of either working without cycloplegia or abandoning the patient to his own devices, it seems to be much safer to make the use of cycloplegia a routine measure than to use it only exceptionally or not at all.

The general relaxation of eyes under cycloplegia seems often to be more complete several hours after administration of the cycloplegic (namely, at a time when the accommodation has partly returned) than within the first hour or so, when the loss of accommodation was at its height. This difference may be due partly to a cerebral reaction, the brain having more completely broken away from the constant attempt to obtain clear vision. Be this as it may, another examination several hours after the first under cycloplegia is often most useful in checking up doubtful details.

The question of how much of the difference between the precycloplegic and the cycloplegic test is to be prescribed must be decided by each ophthalmic physician according to his personal experience and predilection. To each one who is debating this question I would say: Be sure that you have used the fogging technique, including bilateral fogging, to its full possibilities. I should like further to urge the method of fogging even under cycloplegia, in order to avoid being misled by any fraction of unrelaxed accommodation.

Sometimes, after examining in succession several cases that show agreement between the precycloplegic and the cycloplegic test, I encounter a patient for whom, for some reason, I have prescribed lenses without cycloplegia, but in whom complaint leads to reexamination under

* Further experience with such a combination, using 5-percent homatropine solution, has been on the whole very satisfactory.

cycloplegia, with marked change of correction and greatly increased satisfaction to the patient.

A recent interesting experience was the case of a highly intelligent schoolgirl, 15 years old, in whom I had used homatropine without getting much difference from the precycloplegic examination. The correction thus found gave some but not complete relief from eyestrain. The patient had a moderate compound myopic astigmatism. I subsequently resorted to hyoscine, 1:240, and found in the right eye 0.25 D., and in the left eye 0.37 D., more astigmatism, with slight modification of the axes. The change made the patient much more comfortable. Contrast such an experience with the statement made by Gjessing, about 10 years ago, to the effect that "the use of weak cylindric glasses, which in the United States of American is so 'modern,' is certainly in many cases entirely useless."

A second instructive case was that of a 64-year-old lawyer who, without a cycloplegic, and in spite of repeated careful tests, varied from 177 degrees to 5 degrees in statement of the axis of a -5.00 D. cylinder. Under homatropine, 2.5 percent, instilled six times the axis of this his only good eye gave a steady record at 180 degrees.

May I stress here that the advantages which might have been derived from the cycloplegic test are too often sacrificed through an exaggerated fear of the patient's inability to become accustomed to wearing any greater correction than that readily accepted by each eye at the postcycloplegic test. Some refractionists never prescribe a full correction for the amount of hyperopia found under cycloplegia, and I have even seen a hyperopic converted into a myopic prescription, the result of a hurried postcycloplegic test.

Courage as well as understanding on the part of the refractionist is necessary. Too many workers fear the struggle with

a reluctant patient. In children the intelligent coöperation of the parents is essential and is not always easily secured. It should not be forgotten that the patient's most difficult time is likely to be just when the effect of the cycloplegic drug is wearing off, for at that time the accommodative power has been only partly restored, and the strain placed upon this incomplete power of accommodation is particularly apt to set up a spasm which blurs distant vision. The final conclusion as to the practicability of a full correction should not be arrived at until after the glasses have been worn constantly over a prolonged period.

Some of the grossest refractive mistakes are committed in dealing with cases of strabismus. If a full correction as found under cycloplegia is ever necessary, it is in the case of convergent strabismus. The correction here prescribed should be precisely that found for each eye, regardless of the presence of amblyopia in one eye. It is altogether illogical to correct fully the amblyopic eye, and at the same time to undercorrect the better eye; or, on the other hand, to correct fully the amblyopic eye while overcorrecting the seeing eye, in the hope of making the two eyes see equally. Both eyes should be corrected on the principle of making them emmetropic in optical construction in combination with the correcting lenses, and by no means on the false principle of giving them both equally poor vision with correction. Only by such artificially produced emmetropia can the brain be given opportunity to coöperate upon the basis of the accommodative effort required.

I do not believe that we can afford to neglect the advantages to be derived from the use of cycloplegia, although in case of necessity we should be competent to make a noncycloplegic examination with the greatest possible accuracy.

530 Metropolitan Building.

DISCUSSION

DR. GEORGE F. LIBBY, San Diego, California: Dr. Crisp has given an excellent paper. I want to mention one point that we both learned from Dr. Edward Jackson; that is, in using homatropine to obtain cycloplegia it has been the custom of all three of us to use a 3-percent solution, warmed to about body temperature, and applied by raising the upper lid and putting a drop at the upper margin of the cornea. Dr. Jackson believes—and I am inclined to agree with him—that we secure better absorption by putting homatropine at the upper edge of the cornea, and holding the upper lid until the solution trickles down over the corneal surface. It has been our custom to instil one drop in each eye every five minutes until six drops have been instilled into each eye. By that method we feel that we obtain complete and satisfactory cycloplegia.

I want to mention one other point that the late Dr. Robert L. Randolph advocated, that is, the instillation of a drop of 0.25-percent solution of eserine after each refraction under cycloplegia. It gives the patient comfort and reassurance, and removes any element of danger from the cycloplegic.

DR. W. B. LANCASTER, Boston: I agree with Dr. Crisp that there is a too general adoption of the belief that cycloplegia should be used in almost all cases, especially in children, and I should like to adduce some additional arguments in favor of omitting cycloplegia in many cases.

What do we use cycloplegia for? We use it to control accommodation. Why do we wish to control accommodation? Because accommodation, by contraction and relaxation of the ciliary muscle, changes the refraction which we are trying to measure, increases myopia, and decreases hypermetropia. For instance (I am going

through the A B C's to start with), suppose a patient at the age of 20 is examined without a cycloplegic and we find in the right eye +2 D. with vision 6/5, and in the left eye +2 D. with vision 6/5, and, testing both eyes together, +3 D. with vision 6/5. If we gave a cycloplegic, perhaps we might obtain a vision of 6/5 with four diopters. What difference would that make in your treatment? You certainly would not give four diopters correction in a patient 20 years of age who had never worn glasses. One would give somewhere between two and three diopters, according to various conditions that the case might present, so that in this case cycloplegia has not given any help.

You would perhaps retort, "Yes, it has given me a good deal of help because it has shown me that there is no astigmatism." How does accommodation affect astigmatism? The best book in German on accommodation and refraction is the one by von Hess. He states that accommodation is not capable of producing astigmatic change in the lens so as to correct an astigmatism. Duke-Elder, who has written the best textbook in English, is of the same opinion. Accommodation—contraction of the ciliary muscle—does not produce an astigmatic change in the lens so that it can correct existing astigmatism. Luedde, who, perhaps, has given more attention to this subject than any one else in this country, is very positive in this regard. We know that accommodation can neutralize astigmatism in some cases, but it does not do this by an unequal contraction of the ciliary muscle producing an astigmatism of the lens which corrects an existing astigmatism. It simply moves the whole conoid forward or back so that different portions of it fall on the retina. If the interfocal circle falls on the retina, then all the lines will

be equally distinct or equally slightly blurred, but accommodation does not neutralize the astigmatism by an unequal contraction of the ciliary muscle. If it did, it would be easy to determine the fact. I reported a case before this Society about 20 years ago in which I did measure this, or rather, in which Souter measured it for me, but that was a very unusual case—a case of paralysis of the third nerve.

DR. HARRY S. GRADLE, Chicago: May I take the liberty of differing with some statements that Dr. Lancaster has made as regards the lack of necessity for the use of cycloplegics in the majority of cases? Patients come to the ophthalmologist for the last word regarding their eyes. It is true that a large percentage of them can be refracted adequately without cycloplegia, but it is equally true that no eye can be examined thoroughly without the use of a cycloplegic. I believe that it is necessary for the ophthalmologist to know more about any eye that comes to him than any general or nonmedical practitioner can know about such an eye; and, secondly, it is necessary not only for that individual eye, but also as a preventive against future trouble, to use cycloplegia. A large percentage of blindness could be prevented by the early use of cycloplegia, particularly in the early detection of glaucoma. I do not believe that the American Ophthalmological Society should go on record as opposing the routine use of cycloplegia for the examination of the eyes.

DR. EDWARD JACKSON, Denver: The question of whether or not to use cycloplegics depends on whether we want to know all that we can know about the eye for which we are prescribing; or whether we are content to follow certain rules that have been laid down for us, without ascertaining what conditions might be disclosed about this particular eye or this

particular patient. We can always learn more by the use of cycloplegics than we can learn without them.

The use or the nonuse of cycloplegia often depends on the patient's resistance to its employment. We should know certain things and consider them with reference to the eye under cycloplegia. A partial correction is not a correction of the error of refraction. Every patient with a partial correction of myopia that I have seen supplemented this partial correction by looking obliquely through his lens. In this way he obtained the effect of a stronger lens, but often at the cost of inducing astigmatism, which was against the comfortable use of his eyes. Patients, however, learn this trick in order to see better, and avail themselves of it. The same effect of looking obliquely through the lens is responsible for a large part of the dissatisfaction of the hyperopic who are given a full correction. When they gaze obliquely through the lens, they have an overcorrection. If we know all that we can know about the case, we can consider these things and are in a better position to reach a sound judgment as to what glasses are needed and how constantly they should be worn.

One other point is overlooked. Every one probably is able completely to relax his accommodation when he falls asleep. He can learn—and I have had this fully illustrated by many cases—to relax accommodation completely and see through his glasses more quickly than he can learn to use a lesser amount of accommodation and see clearly through partially correcting glasses. For patients in general an unaccustomed partial accommodation is more difficult than complete relaxation. Patients often endeavor to become accustomed to a partial correction, but are unable to see with the lenses after months of trial. When the full correction is given, however, with a little caution as to look-

ing through the center of the glasses, they will return in a few weeks to report that the lenses are satisfactory. Most persons can relax accommodation when they go to sleep, and it is easier for them to learn to relax accommodation and see clearly with the full correction, than to relax partially and see clearly with a partial correction.

DR. W. H. CRISP, closing: As regards Dr. Lancaster's comment on the patient who is supposed to show two diopters of hyperopia, taking each eye separately, and three with both eyes together, and four with cycloplegia, and Dr. Lancaster's statement that we should certainly not give him four diopters, I would say that I most certainly should, after I had warned him that he might have difficulty in learning to use the full correction. A patient came to me who had never worn glasses. Under cycloplegia he accepted +5.50 D. spheres at the trial-case. I did not want to make it too difficult for him, so I deducted a half-diopter and gave him +5.00 D. spheres. I told him he might have trouble in becoming accustomed to the lenses. Three months later he returned complaining of some residual discomfort. I tested him at the trial-case and he accepted +5.50 D. spheres again, so I gave him an extra quarter-diopter which brought comfort. To another patient who had worn +0.75 D. spheres I gave +1.25 D. or +1.50 D., and he was more dissatisfied than the patient who was given five diopters. You cannot tell until the patient tries, and surprises occur all the time. There are children who take

a one-diopter plus sphere and who, in spite of all the efforts of the parents to have them wear the glasses constantly, still show a definite blurring in reading the test letters after wearing the glasses for some time. We must decide for the individual case, but we are not giving the patient a fair chance unless we endeavor to have him wear the full correction.

Can accommodation correct astigmatism? It has been stated that it cannot. I do not know of anything that has been done to prove that accommodation cannot correct astigmatism. I do not believe that if you have a half diopter of astigmatism the accommodation is capable of correcting it; but suppose that by action of one part of the ciliary body the accommodative action can alter the astigmatism by only a quarter or even an eighth of a diopter—that patient is going to experience eyestrain. Even though the involuntary effort can only go one eighth of a diopter toward correcting the astigmatism, the patient may experience trouble from making this constant effort, and I am sure many eyes do undergo some such change part of the time. We must also consider the action of the eyelids in correcting astigmatism.

As to the use of eserine: here and there I find someone who uses not merely one drop of eserine, 1:240 solution, but two drops of eserine of that strength. I have instilled two drops, and some patients had a very uncomfortable time, so in the case of most adults and adolescents I merely use one drop after homatropine.

A GLARELESS ILLUMINATED HOLDER FOR VISUAL-ACUITY TEST CHARTS WITH VARIABLE INTENSITY OF LIGHT*

C. E. FERREE, PH.D. AND G. RAND, PH.D.

Baltimore

At various times we have been requested by members of state, municipal, and college health departments to give some attention to equipment for testing vision in the schools and for similar purposes. In particular we have been asked to try to devise an inexpensive, easily portable chart holder that would be completely glareless and would provide a glareless, well-distributed, even illumination of the test chart of a correct and standard intensity. It is our purpose in this paper to describe such a chart holder.

There are, in our judgment, the following needs for a careful selection of an equipment for testing vision in the public schools. (1) Customarily in school testing no attempt is made at a complete refractive correction. The test of vision must be depended upon entirely to indicate the condition of the pupil's eyes, to detect whether the condition is getting worse or better in case there is a refractive defect, and to decide whether there is need of reference for a medical examination. There is a poor chance to accomplish a satisfactory result if the conditions of making the test are not standardized and uniform from time to time and from place to place. For example, we find there is great uncertainty at the present time as to just what is normal acuity for children at different ages. The feeling of uncertainty is due to the fact that it is well known that the conditions of making the test are not the same from time to time and from place to place in examining the same child. Also, if the test conditions are not satisfactorily standardized, one cannot tell in examin-

ing the child in different years of his school life whether his condition is the same, better, or worse. From this it can readily be seen that careful attention to consistency in vision testing is more important in the schools than it is to the doctor in his routine practice. That is, the doctor is prepared to make a complete refraction and does not, therefore, have to depend so much upon the standardization of his conditions for testing and rating vision. Further, the refractionist's job is to give the best vision it is possible to obtain by means of a correcting glass providing there are no auxiliary reasons for prescribing otherwise, and in consequence he is not so dependent on what is accepted as the normal rating of vision nor on any previous rating he has made. (2) There is a great deal of practical and scientific need for knowing what vision is at different ages and what should be considered the norms of vision at these ages, particularly during the formative period and beyond middle life. In this we are personally very much interested, and it is one of our strongest motives for trying to secure standardized and correct test equipment. Very important means of obtaining a part of this knowledge are the examinations that are made systematically in the schools—grade, high school, and college.

The two most important variable factors in vision testing are (a) type of test chart used and lack of uniformity in these charts, and (b) intensity of illumination of the chart and its wide variation from place to place and time to time. Of these the more important is intensity of illumination. Apparently the testing from the kindergarten through college is in a

*From the Research Laboratory of Physiological Optics.

very unfavorable condition. A great variety of test equipment is being used, and very little attention is paid to the standardization of the illumination of the test charts. Results obtained under these conditions are, of course, of little value from the standpoint of comparative ratings or the determination of anything approximating a set of norms.

The lighting device which is used on our chart holder consists essentially of two boxes of special construction and of suitable location in relation to the surface to be illuminated. It was planned for three purposes: for the illumination of pulpits and speakers' desks, for the illumination of test charts, and for the illumination of music racks. It is the application to test charts alone that will be discussed in this paper. This application is shown in figure 1.

In figure 1 are given (a) an outline

Fig. 1 (Ferree and Rand). A, an outline drawing of the chart holder showing the location of the lighting boxes and their relationship to the surface to be illuminated. B, drawing showing a cross section of the chart holder. C, drawing showing a set of the vanes or glare baffles used on the inner side of each lighting box.

drawing of the chart holder showing the location of the lighting boxes and their relationship to the surface to be illuminated, (b) a drawing showing a cross section of the chart holder, and (c) a drawing showing a set of the vanes or glare baffles on the inner side of each lighting box. In figure 2 are shown larger lighting boxes of the same type built into a portable unit for use on lecture tables and speakers' desks.

Some of the faults in the present illuminated chart holders are: excessive glare from the lighting device; glare on the surface of the chart; a very uneven and poorly diffused illumination on the test surface; high light and brightness on the lateral edges of the chart and near to the illuminating units; an unstandardized and a too high intensity of light; and lack of portability.

Our chartholder has been especially designed to correct all of these faults. This has been accomplished in the following ways:

(1) The eyes are shielded from glare from the lighting units by vanes or glare baffles, properly inclined, on the inner side of each lighting box. Further to complete the glare protection, both surfaces of these vanes are surfaced in flat black.

Fig. 2 (Ferree and Rand). Large lighting boxes of the same type as are shown in figure 1, built into a portable unit for use on lecture tables and speakers' desks.

(2) Diffusion of the light is secured by placing behind the vanes a plate of diffusing glassware, probably Celestialite glass, because this glassware not only gives excellent diffusion of the light but also all the color correction that would be needed. It is a comparatively thin plate, light in weight, made of 3-ply glass, the two outer plies of opal glass and the intermediate ply of blue glass. An etched plate of Daylight glass could be used, but this would be expensive.

Diffusion of the light is, of course, a very important factor in securing evenness of illumination of every part of the chart and of the floor of the chart holder. By minimizing specular reflection, this diffusion is also an important factor in eliminating glare from the test surface. The elimination of glare is further effected by the direction of light, so that none of the specularly reflected rays can

enter the eye. A still further benefit along this line can be obtained by covering the floor of the chart holder with white blotting paper or other mat material. This would be of service in cases in which the chart is not so broad as the floor of the chart holder. Diffusion, too, gives high visibility to the test objects themselves. For clear vision, light from every point in the object must be brought to a focus in the image formed on the retina. For this to take place, every point in the object must be adequately illuminated. Adequate illumination for each point is secured only with well-diffused light. Finally, the diffusion of the light serves to eliminate all shadows that might otherwise be cast by the inclined vanes.

(3) High light and high brightness on the floor of the chart holder near the two lighting boxes are prevented by a thin strip of metal of suitable breadth walling

off the luminous aperture up to the lowest vane. Thus the right side of the chart holder will receive its illumination chiefly from the lighting box on the left, and the left side will receive its illumination chiefly from the lighting box on the right. In the experimental model of the device, the vanes should be made adjustable in order to ascertain the exact angle of inclination at which they should be set to secure both glare protection and the proper direction or placement of the light. Direction of the light is further aided by an inclined, diffusely reflecting plate of Alcoa aluminum mounted at a suitable angle above and behind the lamps.

(4) In manufacturing the lighting boxes, the standardization of intensity can be secured through a careful selection, seasoning, and location of the lamps employed* and the use of diffusing glassware of the needed density. In this latter connection more than one plate of glassware may be used, the plates having the same or different densities, as may be required. The manufacturer has, of course, to see to it that this standardization is secured in all chart holders that are put on the market.

(5) Easy portability can be had by making the chart holder of thin, hard-sheet aluminum and using care in the selection of other material and in the construction to keep the weight down.

The holder should be made so that any standard chart can be used. The chart which we have recommended, however, as especially suited for the correct and reproducible testing and rating of vision is the double-broken circle chart described in a former paper.¹ In a later model the test objects have been rearranged so that all the sizes can be included, with a suffi-

cient number of each size, in a chart 10 by 28 inches.

The feature of variable illumination can be added, if desired, with very little change of construction. One of the advantages of adding this feature is the ease it would afford for securing the intensity that is chosen as standard. This advantage alone might render the construction of the holder less expensive than would be the case if the standard intensity had to be secured by the means noted in (4) above. The following change in the construction is all that would be required. An inside wall of thin aluminum could be added next to the diffusing plate. At a suitable height in this wall a longitudinal slot or aperture could be cut of suitable breadth and of a length almost equal to that of the boxing. In this aperture would be inserted a single vane of thin aluminum mounted along its central axis on a slender rod, the ends of which pass through the top and bottom of the boxing. On the upper end of this rod will be mounted a button by means of which the vane can be rotated. As the vane is rotated from a position normal to the diffusing plate to the parallel position, the intensity of light is varied from full to approximately zero. A good diffusing plate such as Celestialite glass will be quite sufficient to eliminate the shadow cast by the vane. With this construction it is quite probable that fewer glare baffles would be needed to shield the eye from the brightness of the diffusing plate, inasmuch as a smaller part of the plate is illuminated to a brightness. Perhaps, indeed, only one glare baffle would be needed.

An intensity scale can be provided as follows. On the top of the boxing may be mounted in upright position an arc-shaped rim of metal on the front surface of which graduations are marked. Beneath these graduations a slot is cut to

* Best results can be obtained with tubular lamps. These lamps are readily available in suitable lengths and wattages.

receive a pointer that is attached to the rod supporting the rotating vane. At the front end this pointer is bent upward to indicate the graduations on the scale. So positioned, the scale can easily be read by the examiner.

The holder should not be expensive to make. If light-weight aluminum is used and care taken throughout in the selection of the auxiliary material, the weight should not be more than 5 to 10 pounds.

With respect to the cardinal requirements: correctness of illumination, easy portability, and moderate cost, the holder will, we believe, give a high degree of satisfaction.

There is an important use of such a chart holder by refractionists. By preference many refractionists still use and always will use a printed chart. We do not hesitate to say that in our opinion and experience the best test conditions, particularly for visual acuity, are given by a properly illuminated printed chart. With it, a better state of adaptation may be had, a clearer definition of the test object, a better diffusion of light and a better background for seeing the test object than can be had by any other type of test equipment. Provided with the feature of variable illumination, ideal conditions for testing vision and for detecting and correcting errors of refraction are obtained with the printed chart.

In this latter connection the very great importance of making the test at low illumination will be remembered.² The refractionist who uses medium or high intensities of illumination for detecting errors of refraction is working against himself. By giving greater power to discriminate detail, the higher illumination enables the test object to be seen even when its image is blurred. It is not hard, for example, to convince a presbyopic subject with blurred images for near seeing, what the effect of high illumination is

on the clearing up of blurred images or, conversely, how impossible it is to see the details of near objects at low illumination. Obviously, then, when one wishes to detect small defects in the image or to decide which of two correcting glasses gives the better result, a low illumination should be used. This is particularly important in case of astigmatism when one is trying to decide what is the proper strength of correcting cylinder and the best placement of its axis.

The use of intensity of light in refraction is just the reverse of what it is in lighting. In lighting, intensity is used to compensate for errors in the formation of the image; in testing and correcting for errors in refraction, it is used in a way that will most clearly reveal these defects. In earlier days there was great confusion on these points. In refraction, as well as in lighting, the tendency was to use high intensity of light and to give the clearest vision of the test object. Happily, today we know that this is not the correct procedure.

This chart holder would also be of a great deal of service in all places or stations in which there is a problem of the accurate and reproducible testing of visual acuity; such, for example, as in motor-vehicle departments, in the testing of railroad employees, in the air service of the Army and Navy, and in the commercial air service. In all cases where there is a need of a standardized requirement of service, there is a corresponding need of a standard testing of fitness for that service.

Perhaps the most widely used test of human powers is that of acuity of vision. In proportion as it is widely used there is need to provide a foolproof equipment. As the situation now is, the testing of vision is one of the most loosely conducted tests we have. Not only has there been no substantial change in the princi-

ples and procedure of making the test since the days of Snellen, but even the principles laid down by him are not complied with in a very great part of the testing that is now being done. So far as restriction or supervision is concerned, almost any type of test chart may be used under any type or intensity of illumination. The variable difficulty of task to which the eye may be subjected under these conditions of testing is a sufficient guarantee that consistency of result will not be obtained in testing the same person at different times and in different places, and that the test will not serve the important purpose for which it is intended.

With respect to type of test chart, it may be noted that capital-letter charts are sold and used without difference or distinction, some having letters constructed to meet the 1 to 5-minute requirement of the Snellen rating scale and others not meeting this requirement even when manufactured and sold by the same firm. Moreover, letters of the same size selected for use as test objects may in the different charts of each of these types, set a very greatly different discriminative task for the eye. Inaccuracies in the dimensions of the letters used are also of frequent occurrence. In former papers^{1, 2} all of these matters have been discussed by us in considerable detail. We have discussed among other things the nature and principles of the visual-acuity test and what it should accomplish; the effect of type of judgment on the results of the test; comparative merits of different test objects, pointing out in particular the futility of trying to standardize the capital letters as test objects or to make of them a correct rating scale; the effect of intensity and composition of light on the results of the test; factors influencing the sensitivity of the test; and comparative merits of different ways of securing the test field.

Obviously the first step in reforming a bad practice is to provide test equipment that so far as possible will not permit of this practice and to make this equipment easily available to the public. It is with this purpose in mind that we have described in former papers, as already indicated, a test object and test chart that will give a correct and reproducible measure of the eye's power to discriminate detail, and in this paper an inexpensive chart holder which will provide proper conditions of illumination and will be easy and convenient to use in a wide variety of test situations.

SUMMARY

Some of the faults in the present illuminated chart holders are: excessive glare from the lighting device; glare on the surface of the chart; a very uneven and poorly diffused illumination on the test surface; high light and brightness on the lateral edges of the chart and near to the illuminating units; an unstandardized and a too high intensity of light; and lack of portability.

The chart holder described in this paper was devised to remedy these defects. A simple mechanical provision is also made for varying the intensity of illumination in continuous change from approximately zero to full without change in the color, composition, or placement of the light.

The following are some of the situations in which there is an important need for such a chart holder. (a) In all cases where there is a problem of the accurate and reproducible testing of visual acuity; such, for example, as in motor-vehicle departments, in the testing of railroad employees, in the air service of the Army and Navy, and in the commercial air service. A particular and very important case of this need is in the testing of vision in the public schools, where customarily

no attempt is made at a complete refractive correction and all knowledge of the pupil's eyes and all advances or recessions of any condition, refractive or otherwise, is dependent upon the testing of vision. Apparently this testing from the kindergarten through college is in a very unfavorable condition. A great variety of test equipment is being used and very little attention is paid to the standardization of the illumination of the test charts. Results obtained under these conditions are of little value from the standpoint of comparative ratings or the determination of anything approximating a set of norms.

(b) In the correction of errors of refraction.

By preference many refractionists still use and always will use a printed chart. The best test conditions, particularly for visual acuity, are given by a properly illuminated printed chart. With it, a better state of adaptation may be had, a clearer definition of the test object, a better diffusion of light, and a better background for seeing the test object than can be had by any other type of test equipment. Provided with the feature of variable illumination, ideal conditions for testing vision and for detecting and correcting errors of refraction are obtained with the printed chart.

THE PRACTICAL MEASUREMENT OF ACCOMMODATION AND CONVERGENCE

HILMER G. MARTIN, M.D.

Milwaukee, Wisconsin

The measurement of accommodation and convergence need not be time consuming nor fatiguing to the patient in the performance of routine refractions.

To be guided by an accurate determination of the amounts of muscle function in constant use, their maximum functions, their reserve power, and their relationship to one another is by far more important than to regulate modification of the refractive correction by considering the position of rest alone.

An instrument, partially described in a previous communication,* has been devised to facilitate the measurement of the following functions in routine practice:

Interpupillary distance

Accommodation: expressed in diopters and read directly

Maximum: monocular and binocular

Amount in use at work distance

Range

Region

Relative: positive and negative elements, at any specified near-work distance

Reserve

Comparison of the near add requirement to accomplish equality in presbyopic subjects

Convergence: expressed in meter-angle terms and read from chart

Maximum

Amount required at work distance

Amount required at near point of convergence and accommodation

Amount required at any near point

Reserve at work distance or any

near-work distance

Amplitude

Comparison of accommodation in diopters and convergence in meter angles:

Maximum

Relative, at work distance or any near point

Reserve

APPARATUS

Three parallel rails, calibrated in diopters and marked in centimeters, are mounted upon a tiltable-beam unit and are adjustable in all directions. Lens cells and carriers for various indicia are mounted upon and are movable on the upper parallel rails. The instrument has been described and illustrated in the reference.

TESTS

Interpupillary distance: The lens carriers are set before the eyes at the mark "O" on the scales. The plano lenses with bisecting scratch marks are then inserted into the lens cells. Sighting from the ends of, and along the rail at the eye being tested (each is done separately), the centers of the lenses are made to coincide with the center of the pupils by raising or lowering the scales and bringing them in or out. The removable plate is then put in place, resting upon the upper surfaces of the rails with the spirit-level side toward the nose piece, the lens carriers having been moved along the scales a very short distance to permit placing the plate between them on the nose-piece. The lens carriers are placed in contact with the plate. Sighting through the upper open grooves, the interpupillary distance is

* Martin, H. G. *Amer. Jour. Ophth.*, 1938, v 21, Feb., p. 161.

read off in millimeters. The plate is then placed at the other end of the scale just in front of, and in contact with, the card carriers, and the scales are brought in or out, raised or lowered, to correspond with the pupillary distance. The plate is then removed.

ACCOMMODATION

Maximum Accommodation

Monocular. With one eye occluded, the patient is instructed to fix the gaze upon the test type on the card, which is placed well out along the scale. The examiner then slides the card carrier slowly along the rail toward the eye until the point is reached where the patient can no longer read the test type and the reading on the scale is taken in diopters. The opposite eye is then tested in the same manner. This is, of course, an application of the Prince-rule method. These tests are made without and then with the proposed correction in the lens cells. Referring to any of the textbook charts comparison with age normals can be made. Any difference between the case reading and that of the age-group normal represents in diopters the spherical strength necessary to bring the patient's maximum accommodation to the normal.

To determine the amount of accommodation required at any specified near-work distance in centimeters, the card carrier is moved to that point on the scale and the dioptric reading recorded. This reading is expressive of the dioptric spherical-lens strength at the specified distance normally required, or the amount of accommodation in diopters used by the emmetropic eye at this point. The binocular function will be considered later on.

Range and Region of Accommodation

The card carrier is placed at the extreme end of the scale and is then moved slowly toward the eye until the test type is just readable, and this point is read off

on the scale. Continuing to move the card carrier toward the eye from this point, the operator notes the point at which clear vision of the test type ceases. The difference between the two readings shows the range and also establishes the region of accommodation. In presbyopia and high degrees of hyperopia this is especially important, and that lens is given which permits of the greatest range or which provides the desired region. This test guards against overcorrection in presbyopia.

Relative Accommodation

These tests determine the maximum amount of accommodative effort that the eye can exert, and the maximum ability of accommodative relaxation at any specified distance. The former is spoken of as the positive, and the latter the negative element. Positive and negative relative accommodation can be tested at any specified near point within normal or corrected accommodative range by means of the instrument.

Negative Relative Accommodation

Each eye is tested separately. The card carrier is placed at the distance from the eye at which the determination of this function is to be made. A known plus spherical lens sufficiently great to blur the test types decidedly is inserted in the lens carrier before the eye to be tested. The examiner then moves the lens carrier along the scale slowly away from the eye and toward the test card to the point where the patient is just able to read the types, where the motion is halted and the dioptric reading taken. The test is repeated with the starting position of the lens well away from the eye and where the type is clearly readable. The lens carrier is then moved toward the eye until the indicia are no longer readable and the dioptric reading again is taken.

This is to check the former reading. The dioptric lens strength is subtracted from this scale reading and the remainder, expressed in diopters, is the amount of accommodative relaxation possible for the eye at this distance. It is, of course, necessary to correct for the amount of accommodation normally in use at this same distance. This can be read off on the scale at the point at which the card carrier is placed, and this reading is subtracted from the remainder just determined and expresses the *negative relative accommodation* at this specified distance.

Positive Relative Accommodation

Replacing the plus lens in the carrier with a minus lens of sufficient strength to blur the type, the test is conducted in the same way, by moving the carrier toward the test indicia until the type becomes readable, when the dioptric reading is again taken. The dioptric lens strength is subtracted from the scale reading; the remainder expresses in diopters the greatest amount of accommodative exertion possible for the eye at this distance. Correction is again made for the normal amount of accommodation in use at this distance, but this figure is added to the remainder just determined and the result is the *positive relative accommodation* for this specified distance.

Example: Let us suppose that the relative accommodation is to be determined for a distance of 33 centimeters.

Place the card carrier at the 33-centimeter mark on the scale. To test negative relative accommodation, place a 5-diopter sphere in the lens carrier, and slowly move the carrier away from the eye to a point where the type just becomes readable. Suppose this occurs at 11 centimeters, or 9 diopters on the scale. Subtract the lens strength, 5 diopters from 9 diopters. Four diopters, then, represents

the greatest amount of accommodative relaxation for 33 centimeters' distance. However, the normal amount of accommodation in use at this distance is found by reading the dioptric scale where the test card has been placed, in this case, 3 diopters. Subtracting this reading of 3 diopters from 4 diopters just determined, leaves 1 diopter, which is the negative relative accommodation.

To test *positive relative accommodation*, replace the plus lens with a minus-5-diopter sphere, moving it away from the eye until the type is clearly readable. Suppose this point is represented by 6.6 diopters on the scale. The difference between the dioptric lens strength, 5 diopters, and this reading of 6.6 diopters, leaves 1.6 diopters, which represents the greatest amount of accommodative exertion at this distance. Since the normal amount of accommodation in use at this distance is 3 diopters, this figure must be added to the remainder just obtained and the resultant, 4.6 diopters, expresses the positive relative accommodation.

The amplitude of accommodation is then also apparent for this distance.

To insure comfort, the positive must at least equal the negative element at the near-work distance.

This test is made first without and then with the proposed refractive correction. Indication is given for modification of the correcting lens to insure comfort.

The measurement of relaxation or exertion of accommodation at a specified near distance as tested by the method offered here, involves really the *continuous* exertion or relaxation of accommodation to the greatest extent. This effect was found to be more expressive of the actual limitations of these functions, inasmuch as the interchange of lenses of successive strengths, as commonly used, permits of a return to a previous lower

state of activity during these exchanges, often resulting in a fatigue reaction or a stopping-short of the limit of function. Again, if too high a lens strength is used initially, or if the progressive increases are too abrupt, a false end point is often taken as true. For instance, if a patient is able to overcome plus lenses until 4 diopters is reached, it will be found that if an initial lens of 3 diopters is used, the patient fails to overcome this strength even though the limit is actually higher. The method offered here has the advantage of imposing a constantly increasing load uninterruptedly.

The amount of accommodation in constant use, or the amount required at the patient's working distance, can be determined by placing the card carrier at the work distance, and reading this measurement in diopters from the scale. Having tested the maximum amount of accommodation of which the patient is capable, and comparing that figure with the amount of accommodation in constant use at the work distance, the amount of reserve accommodation is apparent. If the amount of accommodation in constant use approaches too closely to the maximum amount of which the patient is capable, the reserve is insufficient and symptoms of discomfort will appear. The existence of accommodative insufficiency or excess are brought out by these tests.

An important test in presbyopia consists in determining the far point of accommodation with the correcting lenses in place, each eye being tested separately. Reference is made, of course, to the farthest point of near-vision range, which should be nearly equal for the two eyes to preserve maximum comfort.

An interesting and important phase of accommodative function, especially in presbyopic eyes, is the measurement of the

Binocular Near Point of Accommodation

The card carriers are removed from the upper scales and, with both eyes uncovered, the patient is directed to fixate the test indicia on the card carrier on the lower and middle rail. This card is slowly advanced from a far position toward the eyes by means of turning the thumb screw on the side of the tubular unit. When the point is reached where the type is no longer readable, the dioptric reading is taken from the upper scale.

In young patients the monocular and binocular near points of accommodation are very nearly the same, but in presbyopic subjects, tested with the near refractive correction in place, the binocular near point of accommodation is definitely and consistently greater than the monocular. The monocular test is made with the visual axes parallel, but the binocular test involves convergence, so we may conclude that the convergence stimulus might account for the greater binocular near-accommodative power. The suggestion is offered that if the binocular near point of accommodation is greater (nearer) than the near point of convergence, there is alternate fixation, which may be too rapid to be observed grossly. The monocular near point is influenced by the state of pupillary contraction, of course, as evidenced by the increased near point when the pin-hole disc is used. For practical purposes, however, the state of the pupil as it obtains in the case under test and at the distance tested is really the guide for the establishment of functional power.

It has been noted in young patients that if the binocular is greater than the monocular near point of accommodation, the condition simulates that of presbyopia, and the positive relative accommodation is generally found to be low.

An increase of .50 diopter sphere or more addition, for near, results in a

greater monocular near point of accommodation; but the binocular is not necessarily increased, although the near point of convergence may be. In many cases, therefore, the binocular near point, with correction, is more important than the monocular reading in consideration of the convergence factor.

In cases of a degree of convergence insufficiency, the near addition which provides a seemingly insufficient monocular near point of accommodation will generally be found to give an adequate binocular near point of accommodation with complete comfort to the patient.

Regional Accommodative Amplitude

Since the term "relative accommodation" is considered by some to mean the relationship between accommodation and convergence for specific distances, the term "regional accommodative amplitude" is perhaps more descriptive, and comments refer to what has been called "relative accommodation" in this paper.

Binocular Relative Accommodation (or binocular regional accommodative amplitude)

With both eyes uncovered, the patient is directed to fixate the indicia on the middle scale card, which is placed at the same mark on the scale at which the monocular tests were made. Then plus and minus lenses of low denomination are placed before the eyes, gradually increasing the strength of the lenses until the indicia are no longer readable. These limits are recorded, and correction for distance made as in the monocular tests.

It has been noted repeatedly that the monocular and binocular end points are not necessarily identical, even in cases in which the monocular regional accommodative amplitude is equal in the two eyes. In many instances the binocular positive element is only half that of the monoc-

ular, while the negative element is the same for both monocular and binocular tests. No cases have been observed in which the binocular positive element exceeded the monocular. In cases in which the binocular was appreciably less than the monocular positive element, the convergence maximum was insufficient. However, some patients with a definite convergence insufficiency manifested equal or nearly equal readings of the positive element, both on monocular and binocular tests. They generally manifested good accommodative function or even an excess.

It is perhaps too elementary to point out that the spherical addition for near vision in presbyopia requires more consideration than merely increasing the correction over the distance determination by some convenient rule of a definite amount of sphere for each year after average presbyopic onset. The indiscriminate addition of equal amounts to each eye routinely, is likewise only an estimate and not a measure of correction. The near correction should satisfy equality regarding the near point of accommodation, the far point, and the range and region in each eye as nearly as possible.

CONVERGENCE

The patient's position is maintained and both eyes are now tested simultaneously, the small card carriers being moved to the far end of the scale or removed entirely.

The middle scale is adjusted so that the first marking on the scale, which is 5, is 5 centimeters from the anterior surface of the cornea.

Maximum Convergence

This phase of the subject has been covered in the earlier paper referred to at the beginning. In it a chart is published which simplifies the use of the instrument.

Reserve Convergence

Noting the amount of maximum convergence and the amount of convergence in use at the patient's usual work distance, the amount of *reserve convergence* is represented by the difference between the two readings. If the amount of convergence in constant use approaches too closely the maximum convergence, there will necessarily be a low reserve, and

CHART 1

CONVERSION OF PRISM-DUCTION POWER INTO
METER-ANGLE VALUES

14	4.36	26	8.07		
15	4.66	27	8.58		

consequent symptoms of discomfort, or limited ability to perform close work with comfort. At least 6 meter angles of reserve should obtain.

Amplitude of Convergence

A chart is appended, in which prism-duction power, determined in the usual way, is converted into meter-angle values. In this way the maximum amount of relaxation of convergence added to the divergence in meter angles, expresses the patient's amplitude of convergence.

Indication is given as to the proper correction which will provide a sufficient reserve and insure comfort to the patient at the work distance.

By these tests the presence of convergent insufficiency or excess is evident.

These tests are performed without the correction to determine the patient's muscular ability, and then with correction to

determine satisfaction of the patient's requirements.

Alternate fixation or suppression is also brought out in the performance of these tests.

COMPARISON OF THE ACCOMMODATIVE AND THE CONVERGENT FUNCTIONS

With the various phases of accommodation expressed in diopters, and convergence expressed in meter-angle terms, the following comparisons can be made:

- Comparison of maximum accommodation and convergence
- Comparison of accommodation and convergence at any near point or usual work distance
- Comparison of reserve accommodation and convergence, maximally, at usual work distance, or any specified near point, which will assist in defining accommodative convergence insufficiency or excess.

In these tests the convergence is kept constant while the accommodation is being determined, and the accommodation is a known quantity while the unknown convergence is being determined. In other words, all other conditions are maintained at a constant while one single function is being determined.

COMMENT

In routine refractions the measurement of phoria and duction is commonly done, although the status of accommodation and convergence, maximal, relative and associated, for near-work distance is for the most part, neglected. The latter functions cannot be surmised from the phoria and duction determinations. Without an adaptable means such as this instrument affords, these tests are necessarily time consuming, fatiguing, and not correlated.

It is a simple matter to include the usual prism appliances for near-duction

as well as for phoria examinations.

Much has been written of the change occurring in the phoria status when the direction of gaze is directed elsewhere than directly ahead with visual axes parallel. Nothing has been recorded in the literature of the effect of accommodation and convergence under these conditions.

This instrument is adaptable for such measurements by tilting the beam vertically, by rotating the chin rest laterally, and readjusting the rails in relation to the changed position of the head.

In cases of accommodative convergence insufficiency the latent period of accommodative action is definitely slowed down, as is seen when testing the positive relative accommodation for near.

In alternating-suppression cases the relative accommodation is generally greater for the fixating eye.

Symptomology is not always proportionate to the existing error. The matter of the reserves offers the best solution.

Patients with a high exophoria, but with a good near point of convergence, tolerate plus corrections well, since the position of rest only is faulty, and normal convergence power is present, although it may be latent. These may be designated as cases of functional accommodative convergence insufficiency.

In duction insufficiency there is generally an accommodative spasm.

In convergence insufficiency there is usually a remote near point of accommodation.

In general, the greater the esophoria,

the greater is the positive relative accommodation; which explains why some patients tolerate a definite imbalance with few symptoms. They usually have a sufficient reserve of accommodation to satisfy overconvergence.

In general, the greater the exophoria, the less is the positive relative accommodation.

As a definitely high exophoria for near becomes less, the convergence near point becomes nearer in young patients.

Spasm of accommodation is often due to the excess convergence impulse necessary to overcome the exophoria.

Accommodative spasm in hyperopic subjects is usually an accommodative convergence excess. The counterpart is observed in patients with so-called relative hyperopia, who acquire strong convergence tendencies when they try to correct the hyperopia by strong accommodation.

CONCLUSION

Inasmuch as a large number of cases of heterophoria are cured or greatly improved by correcting the refraction alone, greater precision in prescribing refractive corrections should be observed, not only in consideration of the positions of rest and ductions, but also with due regard to accommodation and convergence in their various phases, and their respective balance relationships; especially if a definite disproportion of accommodation and convergence exists.

231 West Wisconsin Avenue.

THE REACTION AND BUFFER ACTIVITY OF NORMAL OX LENSES*

P. W. SALIT, PH.D.

Iowa City, Iowa

The determination of the reaction or hydrogen-ion concentration of biological tissues, such as the crystalline lens, is much more difficult than that of fluids. For this reason comparatively little work has been done on the lens. There are many methods for the determination of hydrogen-ion concentration, but only one is fundamental, and against this all other methods are standardized. In this method, commonly known as the hydrogen-electrode method, a platinum foil, coated with platinum black, in the presence of a continuous stream of hydrogen serves as a hydrogen electrode; the other electrode is a calomel cell, consisting of mercury in equilibrium with a paste of mercurous chloride and mercury; the electrolyte is potassium-chloride solution saturated with mercurous chloride. This method, as ordinarily employed, requires 10 c.c. or more of the fluid that is to be tested. It is apparent that the lens, in its original condition—that is, undiluted with water—cannot be used in this method. If, however, the chemical make-up of the lens is such that it can act as a strong buffer, a moderate dilution with distilled water will have practically no effect on its hydrogen-ion concentration. And if, in addition, the lens contains no free carbon dioxide, the pH can be accurately determined on the aqueous lens emulsion by the use of the hydrogen electrode. Sharp and Powell,¹ using the hydrogen electrode, determined the pH of egg white and yolk, both in their original or undiluted condition and also diluted with various amounts of distilled water. They found the pH of undiluted egg white and yolk to be 7.82 and 5.93, respectively; after adding 12 c.c. of

water to each, they were 7.89 and 5.94. When 14 c.c. of water was added to fresh samples from another egg, the respective pH readings were 7.92 and 5.96, and after adding 200 c.c. of water to each, the pH values were 7.93 and 6.23. Evidently the contents of the egg in their natural fresh condition possess remarkable buffer properties; especially is this true with respect to egg white, a dilution from 14 c.c. to 200 c.c. producing practically no change in pH. Since the lens substance, in its physical appearance, resembles that of egg white, it was thought that it might possess similar buffer properties and thus lend itself to the study of its reaction by the hydrogen-electrode method.

In this study the lenses of one-month-old calves and two-year-old cattle were used. Each lens was macerated in a mortar to a homogeneous paste, emulsified in distilled water, and diluted to either 15, 40, or 80 c.c. The emulsion was then transferred to a glass vial just large enough in diameter to contain the two electrodes of the apparatus. A few drops of amyl alcohol were added to prevent foaming on passing a stream of hydrogen through the emulsion.

The pH determinations were carried out on four calf lenses within half an hour after the death of the animals. Each lens was emulsified in 15 c.c. of distilled water, and the hydrogen-ion concentration was determined on this emulsion. Their pH values were found to be 7.55, 7.50, 7.70, and 7.50. Two calf lenses were exposed to the laboratory atmosphere for eight hours, then treated as those just described; their pH values were found to be 7.45 and 7.50, indicating practically no change in reaction. One calf lens that was

* From the Department of Ophthalmology, College of Medicine, State University of Iowa.

emulsified in 40 c.c. of distilled water and tested within one-half hour after death of the animal had a pH of 7.60. The second lens of the same animal was emulsified in 80 c.c. of distilled water, and its pH likewise was 7.60. Ten lenses obtained from two-year-old cattle were emulsified in 15 c.c. of distilled water within two hours after death of the animals. Their pH values were as follows: 7.45, 7.45, 7.45, 7.45, 7.40, 7.50, 7.39, 7.34, 7.37, 7.32, an

7.56 to 7.60. The same difference was shown when there was an increase in dilution from 15 to 80 c.c. When the lenses were exposed to air for eight hours and the pH determinations were carried out on 15-c.c. dilutions, the reaction shifted toward the acid side by only 0.08; that is, from a pH of 7.56 to 7.48, this change evidently being due to slight autolysis of the lens protein. Similar changes were observed in the lenses of two-year-old cat-

TABLE 1
MINIMUM, MAXIMUM, AND AVERAGE pH VALUES OF FRESH AND STALE LENSES

Age of Animal	"Fresh" lenses ($\frac{1}{2}$ to 2 hours after death)			Stale lenses (exposed to air for 8 hours)
	15-c.c. dilution	40-c.c. dilution	80-c.c. dilution	15-c.c. dilution
1 month Averages	pH 7.50-7.70 7.56 (4)*	pH 7.60 7.60 (1)	pH 7.60 7.60 (1)	pH 7.45, 7.50 7.48 (2)
2 years Averages	7.32-7.50 7.43 (10)	7.50, 7.50 7.50 (2)	7.60, 7.60 7.60 (2)	7.40, 7.40 7.40 (2)

* Figures in parentheses indicate the number of lenses studied.

average pH of 7.43. Two lenses from cattle of the same age were exposed to the laboratory atmosphere for eight hours, then emulsified in 15 c.c. of distilled water; each had a pH of 7.40. Two fresh lenses from two-year-old cattle, removed from the eyes within one to two hours after death, were emulsified in 40 c.c. of distilled water; each had a pH of 7.50. Each of two similar lenses that were emulsified in 80 c.c. of distilled water, had a pH of 7.60 (table 1).

It appears from the foregoing data that the lens tissue of calves is slightly more alkaline than that of two-year-old cattle, their respective pH averages being 7.56 and 7.43. The buffer activity of the calf lens is such that an increase in dilution from 15 to 40 c.c. for a single lens produces on the average an increase of only 0.04; that is, an increase from a pH of

7.56 to 7.60. A change in dilution of the lens from 15 c.c. to 40 c.c. resulted in an average increase in pH of only 0.07 (from 7.43 to 7.50), and a dilution to 80 c.c. resulted in an average increase of 0.17 (from 7.43 to 7.60). On the other hand, there was a slight decrease in pH, amounting to 0.03, when the determinations were carried out after the lenses were exposed to the laboratory atmosphere for eight hours; that is, a decrease from a pH of 7.43 to 7.40.

On the basis of the foregoing results it is apparent that practically no change in pH of the normal ox lens occurs with emulsification in 15 c.c. of distilled water. Therefore the electrometric method with the hydrogen electrode is applicable in pH studies of normal lenses that approximate the size of calf lenses, provided there is no appreciable amount of free carbon dioxide. So far, according to my knowledge,

there are no direct experimental data showing whether the normal lens does or does not contain free carbon dioxide. Sauermann² in his pH studies of normal cattle lenses used the Michaelis³ colorimetric method in which precautions were taken to prevent the escape of carbon dioxide. He reports the following pH values: 7.4 for 40 lenses, 7.5 for 7 lenses, and 7.6 for 3 lenses, an average pH of 7.43. This is in exact agreement with the average value obtained in the present work on two-year-old cattle. And although Sauermann fails to state the age of the animals from which he obtained the eyes, it is safe to assume that the latter came from animals of approximately the same age—that is, two years old—for this age greatly predominates in cattle used in abattoirs. It is therefore evident that there is no free carbon dioxide in normal ox lenses.

SUMMARY

The hydrogen-ion concentration and the buffer activity of normal calf and two-year-old cattle lenses were studied electrometrically, using the hydrogen electrode and a saturated calomel cell. In this study it was found that if a single lens is emulsified in 15 c.c. of distilled water, the dilution, on account of the high buffer property of the lens substance, produces practically no change in the hydrogen-ion concentration. The average pH of calf lenses is 7.56 and that of two-year-old cattle is 7.43. The latter figure is in exact agreement with the pH value found by Sauermann for normal cattle lenses by the Michaelis colorimetric method in which precautions were taken to prevent the loss of carbon dioxide. It is therefore concluded that normal cattle lenses contain no free carbon dioxide.

THE DISLODGING FORCE UTILIZED IN INTRACAPSULAR CATARACT EXTRACTION

T. J. DIMITRY, M.D.
New Orleans, Louisiana

It has long been a wonder to me that so few¹ of those gifted in argumentative writings have come forward and expressed themselves regarding the force that is required to remove the lens in capsule from the eye. A knowledge of its application is basic, and the very success of an ideal procedure depends upon knowing just how this force should be directed. I have labored under the impression that its application has been misunderstood, else the giants of learning would have written more instructively as regards their special techniques, so as to rescue those committing error and better qualify ambitious novices. On many occasions, I have analyzed the adroitness of successful surgeons while they delivered the force, and have remembered fundamental teachings regarding the lens attachments and surroundings to conclude that the surgeons did not break the bonds of the lens by pulling on either the lens or its capsule. It is my conviction, after witnessing many operate and after great personal experience, that no matter what intracapsular procedure is adopted the lens is not extracted by the use of force applied as traction.

Unless it becomes fully known "that the lens is not pulled from the patellar fossa," the young surgeon cannot hope to succeed, nor can general acceptance be expected for the intracapsular procedure. The statement is so ostensibly correct that it should pyramid writings on the cataract operation.

Although the capsule of the lens is grasped with forceps in the most popular of techniques, and movements of the hand reveal a pull and zigzagging of the lens from the eye, but little trust should be put

in this particular finesse. Watch the other hand rupturing the zonules by making pressure with a rod or spoon. It is not the force that appears as actual to eye and mind that accomplishes the removal of the lens, but the inapparent push exerted by the rod wedging the lens from the vitreous. You may ask, therefore, why forceps and vacuum discs are used to grasp the capsule, when the capsule is frequently torn in using these instruments; or, what purpose they serve since they do not break the lens from its moorings. Colonel Smith answers that they are unnecessary, "a push applied to the tip of the lens through the cornea is alone essential."

J. Russell Smith¹ witnessed Barraquer using a vacuum disc, "in which the lens was seized and drawn out of the eye in its capsule," without deforming pressure having been applied to the outer wall of the globe. But, upon studying slow moving pictures, it became clear to him that "Barraquer's success could not have been achieved by pulling," for "he dislocates the lens by pushing it bodily back into the vitreous, a course which would impose no strain on the grip of the instrument which it was not fit to stand." He adds that the secret of success depends on "pushing instead of pulling."

Procedures, such as "the combined forceps and expression techniques" of Stan-culeanu, Knapp, Török, Lancaster, and Davis, diminished the "brute force" of Smith. Colonel Smith did not grasp the lens capsule with instruments but applied a hook at the limbus to the lens periphery, making pressure with it to break the attachments between the lens and ciliary processes, using the vitreous for a cush-

ion. The other surgeons directed the force as did Smith, but while doing so passively held the lens capsule so as to have the force transmitted between the lens and vitreous.

Davis says, "... in no way is the force of the combined procedure" (in which the capsule is grasped with forceps and pressure delivered) "comparable to the force formerly exerted in the Smith operation." He further states that the pressure used in the combined techniques "is 95 percent push and but 5 percent pull" yet the push is gentle in that it is directed between lens and vitreous.

A knowledge of this procedure has brought great success to many adopting the intracapsular method, and the want of such information has resulted in failure for others.

It is my surmise, that Smith's superior dexterity lies in manipulating the hook to get behind the lens, although he did not convey this information in his writings, and Barraquer's success definitely did not depend upon a pull, although he used a vacuum grasper. Those using the combined procedure wedge the lens from the vitreous, but do not pull it from its attachments. Barraquer, after rupturing zonules by a push instead of a pull, topples the lens sidewise to direct it out of the eye.

I have adopted and for some time utilized a net for removing the lens in capsule, in fact a zonulatome⁷ that encircles the lens and presses around it, causing the lens to swell up and become ensnared in cross wires. The lens is grasped bodily; but even so the instrument is not used to pull it out. The zonulatome directs the lens after the zonules have been ruptured. I have also developed another instrument. It is very much like Barraquer's grasper, but makes intermittent suction on the capsule, breaking the zonules.⁸ It requires no force, neither pull nor push, to get the lens in capsule from the eye.

Having accounted for the success of the procedures, it becomes necessary to explain why a push on the lens is better than a pull. To do this, I have made models of the eye for demonstrating the different procedures and for creating slow moving pictures. Cords and rubber tubes were used to develop action. The lens, in the fossa of the vitreous, is seen to be fenced by the scleral spur, against which it becomes jammed if direct pull is made. The model with cornea and iris removed, reveals that the lens cannot be made to slide over the scleral fence. It might be caused to mount the fence after the distal side of the lens has first been pushed down into the vitreous; otherwise it is brought over by toppling. If the wedge is inserted between the lens and the vitreous on the distal side, the proximal side acts as a hinge. A revolution of 180 degrees is produced at the hinge when the force follows the lens outward. The scleral spur, which I have designated a fence, is the all-important point in applying pressure. If the force is applied behind the ridge it must accomplish its effect by distorting the vitreous, whereas, if applied in front of the ridge, the force is delivered between the lens and vitreous.

To what extent the applied force may affect the stability of the vitreous should always be kept in mind. Fortunately nature in her wisdom designed a semisolid vitreous inclosed within the scleral envelope the aperture of which is smaller than the diameter of the sphere; hence the normal vitreous must be fractured before it can get out of the eye. If the vitreous has become liquid, the opening made for the extraction of the lens is sufficient to spill it from the eye, for the spherical shape of the eye is changed by the incision into the globe. When the vitreous is liquid it will spill, for a sphere has a greater capacity than any other form of container.

It would be almost impossible to meas-

ure the sustaining strength or the degree of force required to produce fracture of the vitreous, particularly when the normal vitreous and eye are considered. The force applied by Stanculeanu, Knapp, Török, Lancaster, Davis, and others in their respective operations is much greater than they acknowledge. Pressure properly directed is a prerequisite for success. As soon as the zonules rupture, and the probe reaches behind the lens, there is no longer pressure on the vitreous but away from the vitreous to the back of the lens, and slowly the remaining attachments are broken as the instrument follows the lens out of the eye.

The vitreous as a mass maintains itself better against a pushing than against a pulling force. When pushed upon, the

vitreous resists like an elastic body; when pulled upon, its surface tension is weakened, lessening a force that provides greatly for its integrity.

Unless it is known that the lens should not be pulled from the eye in the course of performing the intracapsular cataract extraction, eyes will be lost and the procedure ultimately abandoned. I am convinced that many do not know the importance of this statement. The maneuver used for dislodging the lens should be thoroughly understood by every ophthalmic surgeon. With this in mind, given the deftness of hand required for the intracapsular procedure, there is no reason why the many may not obtain the skill of the few.

NOTES, CASES, INSTRUMENTS

A NEW ORBITAL IMPLANT

WILLIAM BROWN DOHERTY, M.D.

New York

The tolerance of the orbital tissues to foreign materials is well known, and for this reason many substances have been implanted in Tenon's capsule in order to obliterate unnatural folds and depressions in the upper and lower lids. Implants also prevent ptosis, impaired motility, and sinking of the artificial eye. My¹ special interest in this subject developed during the World War, but it is not my intention in this article to discuss the merits of the numerous implants. I wish, however, to call attention to a new implant constructed of an alloy called vitallium; a product of the Austenal Laboratories of New York City.

As metallurgical knowledge² increases, particular alloys are developed for specific fields, and in their applications exhibit advantages of superior properties not obtainable in the constituent metals of which they are composed. Vitallium is a casting alloy, 90 percent of which is composed of cobalt and chromium with a smaller percentage of molybdenum, and is designated as a cobalt-chromium alloy. The alloy is exceptionally strong and hard, very light, and has been found³ to be completely inert and most compatible with living tissue, producing no tissue nor electrolytic⁴ reaction. This has been shown in a series of very interesting experimental studies. Vitallium has a specific gravity of 8.29,—much less than the specific gravity of pure gold, which

is 19.3, or of casting golds, which range from 14.0 to 18.0. This material resists strong mineral acids, and a solution of sodium chloride of any degree of concentration over any period of time produces no effect on it. Vitallium has been used for a considerable time in prosthetic dentistry, and now plates and pins⁵ have

Fig. 1 (Doherty). Vitallium orbital implant.

been most successfully used in the treatment of fractures.⁶ The idea occurred to me that such a material is suitable for orbital implantation, and I presented the first model before the New York Ophthalmological Society during the April, 1938, meeting.

I wish to extend my appreciation and thanks to the Austenal Laboratories of New York for their kind assistance; and to E. B. Meyrowitz of New York for the excellent photograph.

REPORT OF TWO CASES OF UNILATERAL RETINITIS PIGMENTOSA*

S. A. AGATSTON, M.D.
New York

The occurrence of bonafide cases of unilateral retinitis pigmentosa again stirs up the controversy of etiology.

In spite of the fact that numerous theories have been promulgated regarding the pathogenesis of retinitis pigmentosa, no single author has been able to offer an unassailable explanation. The abiotrophic theory is supported by the occurrence of cerebral involvement in atypical cases of tapeto-retinal degeneration but does not go well with unilateral occurrence. The suggestion of traumatic origin of the disease, promoted by Wagenmann's¹ experiments, is not consistent with the statistics, which show that retinitis pigmentosa following trauma is practically unknown. The angiospastic theory is surely unsatisfactory, because it is difficult to conceive the occurrence of arteriolar spasm at an early age and limited to retinal vessels. Also, if this were true, retinitis pigmentosa should be a common occurrence in essential and malignant hypertension, which it is not. Neither does it occur in secondary atrophies associated with optic neuritis, retrobulbar neuritis, or toxic amblyopia. Certain it is that in all typical cases there is gradual occlusion. So constant is this vessel change that without it diagnosis is

impossible. Moreover, so characteristic is the appearance of the disc and vessels, that, in the absence of malignant hypertension, the disease may be recognized before the periphery or pigment spots are seen. The pigment appearance so constantly observed in retinitis pigmentosa is also seen in other diseases, such as retinosis, choroidosis, choroideremia, choriorretinitis, topical senile degeneration of the peripheral retina. The arterial picture, however, belongs to retinitis pigmentosa.

It is not likely that the retinal vessels are narrow because of general atrophy of the retina of which they are really not a part. In diffuse chorioretinitis where practically the whole retina is destroyed, the retinal arteries are usually normal.

It seems to me that if we could find an explanation for the gradual narrowing of the vessels, we would hit upon a workable theory applicable to the etiological solution. We know now that narrowing of vessels with fibrotic and hyperplastic changes is caused by any form of occlusion. Whether that occlusion is produced by an embolus, thrombus, pressure, or spasm makes very little difference. Hence, the vessels found in retinitis pigmentosa resemble those in malignant hypertension, or following intra- or retrobulbar neuritis. In other words, the vessel changes are not secondary to general atrophy but secondary to pressure and occlusion.

We can conceive the occurrence of a topical neurofibromatous formation. Such formation may be limited to the central portion of the optic nerve or may be found elsewhere in the nervous system. This would explain the cerebral cases and

* Presented at the New York Academy of Medicine, Section on Ophthalmology, April 18, 1938.

possible association with otosclerosis. In explanation of this hyperplasia one might draw a parallel with what happens in Von Recklinghausen's disease. Wagenmann's experiments also should not be disregarded. He showed that cutting off the vessels behind the globe in rabbits resulted in pigmentary degeneration. Trauma to the eye could not result in pigmentary degeneration unless by scar tissue; the retinal vessels were compressed. My own experiments on rabbits, consisting of injection of alcohol into the optic-nerve trunk of the rabbit, gave results similar to Wagenmann's.

It appears that sudden blocking of the retinal artery does not produce pigmentary degeneration, but very gradual occlusion occurring early in life (retinitis pigmentosa has its onset between the ages of three and eight years, according to Hoering² and others) causes a gradual degeneration of the periphery with replacement of necrotic spots by proliferating pigment epithelium. This happens because the terminal small arterial branches become fibrotic, and early in the disease lose their patency.

Shoemaker,³ in his monograph, shows a massive hyperplasia within the optic nerve, as a post-mortem finding. In our pathological laboratory at Montefiore Hospital, Dr. Smoleroff and I have been able to demonstrate similar changes. The occurrence of unilateral retinitis pigmen-

tosa, of which there should be no doubt, while it militates against other theories, does not conflict with the theory of intraneural hyperplasia.

Dr. M. N. Beigelman⁴ gives a résumé of 11 cases of unilateral retinitis pigmentosa reported since 1865. In that year the first case was reported by Pedraglia.⁵ The oldest patient was 42 years of age and the youngest 10 years of age.

Case 1. M. W., aged 53 years, complained of poor vision of the right eye for at least 38 years. The right eye showed retinitis pigmentosa with posterior cortical cataract and optic atrophy. Vision O.D. was ability to see hand movements on the temporal side only. The fields of vision of the right eye could not be taken with the largest test object. The left eye was normal with 20/25 vision and a full field. Laboratory tests were negative except for a positive sputum for tuberculosis.

Case 2. Mrs. S. H., aged 45 years, noticed poor vision in the left eye at the age of 14 years. This eye showed a posterior cortical cataract and typical retinitis pigmentosa with sclerosis of choroidal vessels; very thin retinal arteries and "apple sauce" color pallor of disc. Vision was light perception in the temporal field. The right eye was entirely normal as was also the general health.

THE RESULTS OF SQUINT OPERATIONS: A REVIEW OF THE LAST 286 CASES AT THE UNIVERSITY OF OREGON CLINIC*

FREDERICK A. KIEHLE, M.D., AND
G. H. HENTON, M.D.
Portland, Oregon

The review of this series of squint operations performed during the last 10 years in connection with the clinic of the University of Oregon Medical School represents results obtained by a great variety of operators of varying degrees of surgical ability and experience, using various operative procedures. It can thus probably be considered a fair cross section of operative results in muscle surgery the world over. In other words, any deductions possible, apart from such as might suggest improved procedures in our own clinic, are exceedingly general and probably applicable to squint operations everywhere.

The esotropia cases outnumbered those of exotropia nearly eight to one, being 244 as against 31. There were eight cases with vertical phoria. The patients, nearly all children, averaged 10.9 years in age. The proportion of strabismic children to children-clinic-attendance was about 1 in 42. The figures cover only the last 10 years and deal only with nonparalytic cases. The university clinic has been operating since 1931; the Doernbecher Memorial Hospital for Children, connected with the university, was opened in 1926.

These operations were performed by 12 operators, all practicing ophthalmologists, save for a few done by the resident in

ophthalmology, whose qualifications require that he shall have had at least one year of special training before appointment. All major surgery is performed under the supervision and in the presence of the senior clinician in charge.

All types of operations were employed. The total number of so-called "weakening" operations was 214 (170 partial tenotomies, 44 recessions). A total of 250 shortening operations included 43 advancements of various types, 56 resections, 38 tuckings, and 113 cinch operations. Surgery was usually limited to a single eye; in only eight cases were bilateral tenotomies or cinch operations performed. In 17 cases one eye was treated at the first operation and the second eye at a subsequent time. In 186 cases two or more muscles were attacked, while in 92 only a single muscle. Two hundred thirteen individuals were operated on by a single operation; 18 had two operations; two individuals were operated on three times; one, four times; and one, five times.

The average amount of esotropia prior to operation was 27 degrees. By a strange coincidence the same amount (27 degrees) of exotropia also was found. And following operation 13 degrees of esotropia and 14 degrees of exotropia persisted.

One postoperative death occurred. The only other catastrophe in the series involved a patient with an abnormally thin and nonresistant sclera which was cut through at the point of a tenotomy. A uveitis followed and the vision is at present reduced to 10/200.

A comparison of the results obtained by various operators shows surprisingly little variation. An operation by a resident of comparatively little experience produced occasionally a remarkably good result, due partly to good fortune and

* From the Department of Ophthalmology, University of Oregon Medical School. Read at the meeting of the Pacific Coast Oto-Ophthalmological Society, June, 1938, at Victoria, British Columbia.

partly to good supervision.

If any deductions are justifiable from the entire study they are these: that no single operative procedure can be relied upon to produce perfect results in all cases; that dexterity in carrying out any technique is the great desideratum; that the average operator will do well after careful study of his cases to limit himself to a single or at least to a comparatively few types of operation and to perfect himself in these types rather than spread himself out thin by trying one type of operation after another, experimenting with every new procedure suggested; and finally that with experience there develops a surgical judgment and intuition that cannot be expressed in words nor in terms of advice.

STANDARDIZATION OF THE PREPARATION OF EYE DROPS

W. T. HASLER, JR., M.D.
Everett, Washington

It will be undertaken in this paper to form a definite plan, based on scientific research, of presenting a solution for a most neglected problem in the field of ophthalmology; namely, that of standardizing the preparation of eye drops.

It will be observed in visiting hospitals, ophthalmologists' offices, and drug stores, that the preparation and changing of eye drops to fresh solutions is deplorably neglected. One has only to notice the dates of expiration to learn that in many cases a change is long past due or there are no dates at all. Most hospitals, however, apply an expiration date, but this is not the rule in private practice, nor do the majority of druggists apply the expiration-date method in dispensing eye drops to patients. Upon holding these bottles to

the light, all variations of floating sediment can be seen, and when cultured a bizarre number of bacteria, yeasts, molds, and fungi can be grown. These are pathogenic and nonpathogenic.¹ Nonpathogenic bacteria alter the constituents of the solutions considerably; for example, Sabalitschka reports the reduction of a solution of calcium chlorate to a chloride within 12 months,^{2, 3} and potassium chlorate to a chloride in one week.⁴ This did not occur with the addition of a proper preservative. Alkaloids are also altered in their effectiveness according to Tagliavini.⁵ He observed that ampoules of scopolamine and opium become ineffective because, due to improper sterilization, molds had destroyed the alkaloids.

The question can now be stated. Should we not attempt a standardization process whereby, at least in the literature, a simple method for eye-drop preparation can be obtained? Those of us using and dispensing these solutions should insist upon their correct preparation in this standard way; and it will be shown that sterility can be maintained, deterioration lessened, expense reduced, physiological properties instituted, and danger from infection lessened.

Eye solutions are contaminated after being used once or twice, and after two or three days, when cultured on agar plates for 10 to 12 hours, yield many and varied types of bacteria.⁶ This occurs from touching the dropper to the eyelids or from dust particles falling into the solution. The eye solutions usually contain no preservative nor germicidal agent to maintain sterility and there is, therefore, always danger of the transfer and introduction of infection to the eye, particularly pre- and postoperatively.

The germicide and preservative widely used in Europe for sterilization of eye solutions is the Nipagin-Nipasol combina-

tion. These substances are the ester derivatives of benzoic acid: p-oxybenzoic acid-methyl, ester (Nipagin-m); p-oxybenzoic acid-propyl, ester (Nipasol-m). These are organic chemicals which have the aforementioned necessary qualifications and in addition are tasteless, odorless, easily soluble in lipoids and boiling water.⁷ They do not affect the reaction, smell, taste, color, or consistency of the materials with which they are to be used. They are also unaffected by dilute acids and bases, but are affected by strong bases when boiled for a long time. They are fine, white, crystal powders, and will last indefinitely, even in a dissolved state, without impaired efficiency. They also dissolve with a neutral reaction; therefore, they do not affect the pH of the solution.

Nipagin-Nipasol is nonpoisonous and nontoxic to man when used in even larger amounts than are to be used here. They are harmless when used as preservatives for foods and pharmaceutical preparations, and two to four times less harmful than phenol, and without cumulative effects.⁸ These esters were tried on guinea pigs, dogs, and cats before being given to human subjects. From the results obtained with animals, the toxic and lethal doses were computed for humans.

	<i>Toxic</i>	<i>Lethal</i>
Nipagin-m	150 gr.	225 gr.
Nipasol-m	225 gr.	450 gr.

The small amounts suggested in this article for the preservation of eye drops would, therefore, be entirely harmless, and are adequate for preserving and disinfecting the solutions.⁹

These two esters, Nipagin and Nipasol, when combined were found to be the most effective preservatives and germicides of all the benzoic acid esters.² This combination in a 1-percent solution, as found by the author, reacts to kill a mixture of *B. coli* and *Staphylococcus pyo-*

genes aureus within two hours. It was further found that 0.05-percent Nipagin-m plus 0.05-percent Nipasol-m in solution killed these organisms within six days. This also was true when applied to common molds, yeasts, fungi, gram-positive and gram-negative bacilli. Since turbidity is observed in many stock buffer solutions, it has been traced to the growth of a species of *Torula*, which are also killed. Leschke found that a 0.06-percent propyl ester solution (Nipasol-m) would guarantee lasting sterility.¹⁰ As to resistant spores, Eschenbrenner found it possible to kill them with a 0.1-percent Nipagin-Nipasol solution in 15 minutes by boiling at 100°C., while, without using this ester combination, it took four hours to effect the same result.¹¹ Sabalitschka and Böhm compared Nipasol, Phenol, and Tricresol as to their germicidal effects, and found that *Staphylococcus pyogenes aureus*, *B. coli*, and Para-typhoid B., in nutrient agar, were killed in one day with the addition of 0.056-percent solution of Nipasol, while it took a 0.3-percent solution of phenol, and a 0.1-percent solution of Tricresol to do the same.¹²

In reviewing other papers, much evidence was found concerning the germicidal and preservative quality of these esters, with information on various organisms—anaerobes, aerobes, spores, fungi, yeasts, and molds—and in each the organisms were killed with Nipagin-Nipasol combination.^{3, 12, 7, 13}

The recommended dilution for the sterilization of eye solutions is a combination of 65 parts Nipagin-m plus 35 parts Nipasol-m.^{14, 15} This low concentration is sufficient to prevent the growth of new organisms and to take care of those already present; yet to the patient it is nontoxic and nonirritating. It is chemically neutral to the eye solution. One cannot expect to have immediate germicidal effect with this

low concentration; however, it will kill *Staphylococcus aureus* in 24 hours, and will prevent the growth of fungi.

Recently chlorobutinal in a 0.5-percent solution has been recommended for sterilization and preservation of eye solutions. It is doubtful that this will prove useful, not because it may not be a good preservative, but because it stings the eye too severely. In comparison, an eye solution with a Nipagin-Nipazol preservative added gives a slight sting; with an acid buffer, this is less; and still less with an alkaline buffer. All solutions listed in the table, except the zinc salts, produce a mild sting at first; the zinc preparations a distinct smart, but all are followed by a most refreshing sensation in comparison to the effect of contaminated drops, the sting of which is great. This mild sting is not uncomfortable, and should offer no disadvantage. Most adults and children flinch whenever anything is done to the eyes. Chlorobutinal is precipitated from solutions with a pH above 7.5. It is also worth mentioning that the preparation of chlorobutinal is very time consuming to a busy pharmacist because it is difficultly soluble in an aqueous solution.

After selecting the best-known preservative and germicide with the requisite qualifications, which are sound in every respect to date, it is necessary to have all solutions as near alike in pH value to the tears themselves as possible before an eye solution can be called perfect. There must also be a proper buffer value for each eye solution from which the medicaments can best be absorbed. Alkaloids are best absorbed and when used are less irritating in a slightly alkaline solution with a pH of 7.6. This latter subject has been very admirably worked out by Dr. S. R. Gifford.¹⁶ By his permission, I am using some of his solutions (see table), others I am adding for a more complete list and

have compiled them in a simplified table. With this guide any physician or druggist can prepare or have prepared the most commonly used eye solutions. There will be no difficulty in having at all times perfectly noncontaminated eye solutions that will be safe for the treatment of patients in offices, hospitals, and homes.

PREPARATION OF STANDARD EYE DROPS

1. Dissolve by boiling one minute in 1,000 c.c. of double-distilled water, 0.8 gm. Nipagin-Nipazol combination. This makes an antiseptic and preservative water.
2. *To prepare acid buffer solution:*
Boric acid c.p. Gm. 12.4
Potassium chloride crystals c.p. Gm. 7.4
Dissolved in 1,000 c.c. of water as prepared in step no. 1.
3. *To prepare alkaline buffer solution:*
Anhydrous sodium carbonate c.p. Gm. 21.2
Dissolved in 1,000 c.c. of water as prepared in step no. 1.

The following table contains the proper proportions in which to use the buffer solutions to give the eye preparations their correct pH value. Any variation in the amount of the drug used in concentrations which might be used in the eye will not change the pH value. If the alkaline buffer solution is kept in a dropper bottle with a dropper giving 0.05 c.c. to each drop, the dispensing will be easier for the pharmacist.

Drug	Acid Buffer oz.	Alkaline Buffer c.c. or drops	pH Value
Butyn	1	—	5.0
Phenacaine . . .	1	—	5.0
Procaine	1	—	5.0
Cocaine	1	—	5.0
Ardenalin	1	—	5.0
Holocaine	1	—	5.0
Zinc salts	1	.05	6.0
Homatropine . .	1	1.50	7.6
Euphthalmine . .	1	1.50	7.6
Physostigmine .	1	1.50	7.6
Pilocarpine . . .	1	1.50	7.6
Scopolamine . .	1	1.50	7.6
Atropine	1	1.50	7.6
Sodium fluoresceine .	1	8.00	9.0

Shortly after the publication of Dr. Gifford's article on buffer solutions, an experiment was made in which all eye

solutions were prepared accordingly, but it was found a heavier growth of fungi developed more rapidly in the buffer solution than in plain distilled water, therefore, Nipagin-Nipazol seemed to be the only preparation possessing ideal qualities for preserving eye solutions. It is a fact, however, that the damp climate that we have in the northwestern part of the United States is more conducive to bacterial growth, particularly fungi. East of the Cascade Mountains, where a drier climate exists, the growth in such solutions is less; therefore, our problem in this climate is more difficult.

SUMMARY

After consideration of the work done upon this neglected problem of ophthalmology, the following summary is offered:

1. All eye drops when prepared for nonoperative use are contaminated, and bacteria grow profusely in these solutions.
2. In the damp climate of the northwestern part of the United States,

fungi grow profusely in alkaline and acid buffer solutions when prepared without a preservative.

3. Suitable and well-proved benzoic-acid esters are used with the ideal acid and alkaline buffer solutions to preserve eye solutions, kill introduced bacteria, prohibit growth of fungi, and maintain and practically guarantee sterility for long periods of time.
4. Benzoic-acid esters have reliable preservative and germicidal powers and are nontoxic to the human eye.
5. The cost of changing and throwing away contaminated solutions is greatly lessened.
6. A convenient table for standardization and preparation of eye solutions is given.
7. The mild sting in using these preparations is not objectionable.

Appreciation is extended to Mr. George A. Tozer, pharmaceutical chemist, for the preparation of solutions required in this work.

COUNTERBALANCED WALL BRACKET FOR SUSPENDING COMBERG SLITLAMP

GEORGE N. HOSFORD, M.D.
San Francisco

Although the slitlamp and corneal microscope have added enormously to our knowledge of pathological processes in the anterior segment of the eye, I have long been dissatisfied with the available means of applying this instrument to the

over the floor on large rubber-tired casters. I was warned by the agents of the manufacturers of this instrument that the vibration produced by rolling the instrument over the floor would be detrimental to the light source and to the delicate adjustments of the beam. While this may be true, I must say the instrument stood the experience remarkably well and when it was examined a few days ago by Mr. Victor M. E. Koch, vice-president and technical manager of Carl Zeiss, Inc.,

Fig. 1 (Hosford). Counterbalanced wall bracket for suspending Comberg slitlamp.

routine examination of patients. When the slitlamp is kept in a separate room to which it is necessary to move patients whose vision is impaired, to seat them on uncomfortable stools, where it is necessary to adjust the height of the instrument by slow-moving screws and to make many adjustments, the tendency is to omit the slitlamp examination of borderline or presumably normal patients. Some years ago, I insisted on mounting a Gullstrand (Zeiss) slitlamp on a table which rolled

he assured me that the instrument was in perfect condition. This model of the slitlamp is too large and requires too much room to mount in any other manner and still preserve the benefits of the beam as it was originally planned to be used.

With the advent of the Comberg model, however, we have available a more compact instrument which weighs approximately 50 pounds. In looking about for some means of suspending this from the wall, in such a manner that it could be

pushed out of the way when not in use and quickly swung into position before a patient in a treatment chair, it occurred to me that a Pacifix wall-mounted counterbalanced stand would easily solve this problem. I interested Mr. Alfred Abend, of the Pacific X-ray Sales Company, in the matter, and he built a special arm to attach to this stand. A flat metal table measuring $9\frac{3}{4}$ inches by 14 inches, with a felt-covered hardwood top, affords ample space upon which to place the base of the slitlamp and upon which the elbows of the observer may be rested. The stand is firmly bolted to a stout piece of wood 8 feet long, 8 inches wide, and $1\frac{1}{4}$ inches thick; this, in turn, is firmly fastened to the wall. The vertical part of the stand projects out from the wall only 10 inches. There is a range of vertical motion of over five feet, and if the stand is placed one foot from the floor, it is possible to

push the instrument above the height of the tallest patient when not in use. The instrument is counterbalanced so that it moves up and down with the greatest ease, aided by wide vertical bearing surfaces and the roller bearings. The arm is designed to support a weight of 350 pounds, so there is an ample factor of safety, and great stability is secured. Such a suspension has the effect of having the instrument on a universal joint, and it can be used with a facility comparable to that of the hand ophthalmoscope. The many types of hand slitlamps on the market bespeak a demand for a more usable instrument. With this suspension, however, the rather unsatisfactory hand types of slitlamp are rendered unnecessary and the range of usefulness of the Comberg slitlamp is greatly increased.

DR. G. VICTOR SIMPSON, *presiding*

THE USE OF BENZEDRINE IN REFRACTION

DR. HUNTER MCGUIRE, of Winchester, Virginia, brought out the fact that he had, during the past year and a half, examined some 300 cases, using the more recent technique of Dr. Beach. This consists, in patients over the age of 12 or 14 years, in the instillation of one drop of 5-percent homatropine in each eye to be followed in two minutes by one drop of benzedrine sulphate. Possibly a more complete cycloplegia can be induced if another drop of benzedrine is instilled five minutes later. Dr. McGuire emphasized the fact that cycloplegia is complete in one hour and refraction must be done promptly, since the peak of paralysis of the accommodation is reached rapidly and passes rapidly. It was emphasized that among the advantages of this new type of cycloplegic are: (1) fewer drops to be instilled with less annoyance to the physician and to the patient; (2) cycloplegia quite as complete as that with the classical method; (3) rapid return of accommodation. The patient is usually able to read fine print in about 10 to 14 hours and is easily able to return to work in 18 hours.

In patients below the age of 12 or 14 years, 1-percent atropine sulphate is instilled in the office and then followed by one drop of 1-percent benzedrine and five minutes later another drop of 1-percent benzedrine. With atropine the refraction may be done in about an hour and a half. The additional advantages in

this type of cycloplegic over the classical method are: (1) the cycloplegic may be administered in the office and better controlled than in using the classical method; (2) the refraction may be largely done at the first visit as opposed to two or three visits by the classical method; (3) the return of accommodation occurs in four to six days, causing less loss of time in school.

Dr. McGuire emphasized the fact that in his experience the type and size of the refractive error is not a factor in ease of induction of cycloplegia nor in the length of time taken to recover accommodation. Pupillary dilation persists definitely longer than cycloplegia. The use of benzedrine sulphate has caused no rise in tension in any of his series of cases.

Discussion. Dr. Louis Greene summarized the findings in a series of 335 cases seen in private practice. Dr. Greene's technique and views differ with Dr. McGuire only in details. Dr. Greene had been accustomed to using 2½-percent homatropine and found it quite satisfactory. He found that all adult patients had sufficiently recovered accommodation at the end of eight or twelve hours to read comfortably.

Dr. William T. Davis believed that cycloplegia was probably more complete with this procedure than when using the classical procedure unless it were very scrupulously carried out.

Dr. McGuire, in answer to questions, stated that he had seen no toxic effect from the use of benzedrine or from the use of 5-percent homatropine, and that he had not used any miotic, either with the newer method of cycloplegia or with the classical method.

SYMPOSIUM ON THE USE OF SULFANIL-AMIDE IN EYE CONDITIONS

COL. F. H. THORNE gave a general discussion of sulfanilamide, briefly reviewing the history and listing the toxic symptoms and their treatment. He pointed out that he had found, after a not too thorough search, two cases in which sulfanilamide had been used for ocular pathology. Colonel Thorne himself reported a case of prostatitis under treatment in Walter Reed Hospital. The patient, prior to treatment, had 20/20 vision; 400 grains of sulfanilamide were given, and at that time the vision was reduced to 20/200 in each eye, though the eye was absolutely normal otherwise. The patient accepted a +3.50 D. sph. \approx +.50 D. cyl. ax. 180° to obtain 20/20 vision in each eye. The drug was withdrawn and in one week the patient had 20/20 vision and read Jaeger 1 without any correction at 13 inches. Colonel Thorne reports this case as one of spasm of the ciliary muscle induced by the use of sulfanilamide.

Discussion. Dr. Thomas Egan reported a case of gonorrheal iritis in an adult. The patient had a low-grade iritis and during the hunt for a focus of infection, a prostatic massage was performed. The patient immediately had an acute flare-up of the iritis, which was typically gonorrheal. No medication was given other than instillation of atropine and the use of hot applications, plus the taking of sulfanilamide by mouth. In 24 hours the improvement was marked and the patient was well within 10 days, having a vision of 20/15.

Dr. Ernest Shepherd reported a case of streptococcic abscess of the lid in a child three years old. The child ran a septic temperature but had negative blood culture. The infection pointed through the lid near the outer canthus and was incised and drained. The patient was given 140 grains of sulfanilamide,

small blood transfusion, and supportive treatment during the course of four or five days. The case ended with complete recovery other than the loss of skin over a large portion of the upper lid, which now is healing nicely.

Dr. Frank Costenbader reported a case of gonorrheal conjunctivitis in a child. The boy, aged four years, had been admitted to Children's Hospital with an acutely inflamed right eye, lids swollen completely shut, and much purulent discharge. He also had a purulent urethritis of several days' duration. When first seen it was almost impossible to see the globe or cornea because of intense swelling, congestion, and discharge. The patient was given 25 grains of sulfanilamide daily, and in 24 hours was opening the eye without aid, and the infection was 80 per cent improved. Negative smears were consistent after four days but positive urethral smears were obtained up to the time of discharge (12 days).

Frank D. Costenbader,
Secretary-Treasurer.

SAINT LOUIS OPHTHALMIC SOCIETY

DR. ROY E. MASON, *president*

SIMULTANEOUS COLOR CONTRAST AND INSTRUMENT FOR DEMONSTRATING IT

DR. CARL T. EBER read a paper on this subject which will be published in this Journal.

Discussion. Father H. Gruender, S.J., of Saint Louis University, said the modifications of his contrast box introduced by Dr. Eber are excellent. They make it easy to illuminate two contrasting surfaces independently—namely, a small infield and a large outfield—and to regulate with fair precision both the amount and kind of light reflected by each field. What

adds to the value of the instrument is the fact that standard color filters are used both for the infield and the outfield. It is also possible to produce artificially "white" light which approximates the composition of unfiltered sunlight. Thus ideal conditions are created for observing the profound influence which is exerted by the outfield on the infield. In literal strictness the inhibiting effect of the two contrasting fields is mutual but it is proportional to the size of each and to the amount of light reflected by each. Hence by making the infield very small and the outfield comparatively large, and by using very small amounts of light for the infield and comparatively large amounts for the outfield, we reduce the inhibiting effect of the infield on the outfield to a minimum. Thus we can practically consider the infield as the inhibited surface and the outfield as the inhibiting surface. By means of this instrument, then, it is possible to demonstrate experimentally that the characteristic appearance of the infield depends not only on the kind and amount of light reflected by that field and reaching the center of the retina, but also by the amounts and kinds of light reflected by the outfield and reaching the peripheral portions of the retina.

Suppose that we illuminate the infield by four units of "white" light. This light is at its best when the outfield is not illuminated at all: the infield under these conditions looks white. The moment we introduce a small amount of "white" light into the outfield, the infield looks darker. The greater the illumination of the outfield, the darker is the infield. When the illumination of the outfield reaches a certain amount, the four units of light reflected by the infield are below the threshold of vision; the infield looks black. This is brightness contrast.

Suppose we illuminate the infield by yellow light. This light again is at its

best when the outfield is black: the infield looks yellow. If we now introduce yellow light into the outfield, the infield looks a darker shade of yellow. By further increasing the yellow light of the outfield a point is reached where the yellow light of the infield is below the threshold and looks black. This is saturation contrast.

If we illuminate the infield by a small amount of white light, it looks white as long as the outfield is not illuminated at all. If now we introduce red light into the outfield, the infield begins to look bluish green. By regulating the amount of red light in the outfield we reach a point where the infield (illuminated by the same amount of white light) looks a saturated bluish green. This is the first form of color contrast: the neutral color of the infield is changed to a chromatic color. And the color of the infield is always complementary to that of the outfield. By means of this mode of procedure it is possible to make the outfield appear any color. The only proviso is that we introduce into the outfield the color that is complementary to the color desired in the infield.

If we illuminate the infield by yellow light, it looks yellow provided the outfield is not illuminated at all. If we now introduce into the outfield light that is not complementary to the infield, say green light, the yellow infield becomes reddish. If we introduce red light into the outfield, the yellow infield becomes greenish. This is the second form of color contrast.

The importance of these phenomena can be gathered from the fact that it is impossible to avoid simultaneous contrast: in daily life there is always an outfield for every infield. The best we can do artificially is to regulate the illumination of infield and outfield, and this is done by his contrast box with greater precision by the instrument of Dr. Eber. In daily

life we get only the beneficial effects of simultaneous contrast. There are two such effects which need emphasis.

Hering has pointed out that without simultaneous contrast we should not be able to recognize visible bodies by their sensible qualities. Sunlight varies in intensity enormously from morning to noon, from day to day, from month to month, as every photographer knows. A piece of black coal reflects at noon about 50 times as much light as it does early in the morning, and about three times more light than a piece of white chalk does early in the morning. If, then, the sensation aroused by a piece of black coal depended only on the amount of light reflected by it, it should look white at noon, and whiter than chalk does in the early morning. As a matter of fact it does not: it looks about as black at noon as early in the morning. The reason for this is that the illumination of the outfield increases proportionately from morning till noon. This outfield stimulates the peripheral portions of the retina and inhibits the stimulating effect of the infield. It is for this reason that bodies in nature, a piece of coal, a rose, a green leaf, and so forth, have for us a "constant" color in spite of the enormous changes of daylight illumination.

Another beneficial effect of simultaneous contrast is that it makes visual acuity possible. The refractive media of the eye are far from being as perfect as the compound lens of a modern photographic camera is. In other words the best normal eye is slightly astigmatic. But we notice nothing of this "normal astigmatism." For the human eye has the marvelous capacity of correcting this "normal astigmatism" by the rivalry of adjacent retinal areas; that is, by simultaneous contrast. Only when astigmatism goes beyond the slight normal limits is it impossible to correct the defect by simultaneous con-

trast. And only such a degree of astigmatism is called by ophthalmologists "astigmatism," as they understand the term.

It may be possible to use the modified form of the contrast box as a means to detect color blindness, to distinguish the two types of ordinary color blindness, and to distinguish both from color weakness. So far, however, no data are available on this use of the instrument.

Those who wish further details concerning the phenomena of simultaneous contrast, and the correlation of these phenomena with the laws of color mixture, will find this information in Chapter IV of his "Experimental psychology."

THERMOPHORE TREATMENT OF RETINAL DETACHMENT

DR. LAWRENCE T. POST presented 13 cases of retinal detachment treated with the thermophore. Nine of these were surgically successful; that is, the retina was reattached. Previously he had used a different technique in two of these cases, without success. Four of the 13 patients were operated on by others in the Eye Department of Washington University. The method is by no means a cure-all but has certain advantages and is worth studying further. In order to reach far back with the thermophore, there must be a soft eye.

With regard to how much of the choroid and retina is affected by the application, he has made a number of sections of rabbits' choroids after applying the thermophore at temperatures of 160 degrees and 170 degrees for one and two minutes and has been surprised at the sharp-cut lines of reaction. The choroid and retina are cupped in the area of application where the adhesion is formed. Looking with the ophthalmoscope at the point of application of the thermophore there is a white, clean-cut area around which the retina and choroid look normal.

He has never made any section of muscle to which he has previously applied the thermophore. This paper will be published in full in the Journal of the Southern Medical Association.

Discussion. Dr. William Shahan recalled some 30 years ago seeing Dr. Hese using a hypodermic needle to draw out subretinal fluid. He said this was done only because he had to do something and not to cure the detachment. We are just now getting somewhere with treatment of detachments, mostly with diathermy. He has not had a great many cases of his own and he thinks the technique with the thermophore as yet is not perfected. Some cases respond without much surgery. The required temperature is usually from 160 degrees to 170 degrees. This does not produce a very violent reaction, nor much pain, and does produce a good result. In one case he simply applied the heat first and then made the puncture. Reattachment of the retina occurred and stayed that way for three months and then went to pieces.

Dr. Shahan showed his improved thermophore. The conductor in the new instrument will be rather large. In one end is a cylinder, solid brass, soldered in, and the thermophore will be inserted in that end. When using the thermophore at a temperature as high as 170 degrees for a long time, the body of the old thermophore becomes rather hot, so in this new model there is a second jacket placed around the inner jacket and the instrument will remain cool.

Dr. H. Rommel Hildreth reported the results of a laboratory study of the galvanic current as used for retinal detachment. Rabbits' eyes were punctured with the cathode needle, using one milliamperes of current. A central puncture using no current was compared with a series in which the time of application increased from 1 second to 15. All the punctures

appeared alike when examined histologically. At the time the current was applied there was a generous supply of hydrogen bubbles in the vitreous, indicating that the current was acting. From this study, which has been repeated, it would appear that the use of the galvanic current in the treatment of retinal detachment is of no value.

Dr. P. Luedde saw a boy who was injured a year prior to the first examination in June, 1937. At that time he had a macular hole and large flat detachment, so all that existed for visual purposes was the outer field. The thermophore was applied. The field was checked three or four days ago and he had a perfect field except nasally in the upper quadrant, where the thermophore was applied. The thermophore applicator was a 5-by-10-mm. point. The retina at present is entirely reattached.

CASE REPORTS

DR. WILLIAM F. HARDY read reports on the following subjects: 1. Bilateral symmetrical detachments of the retina in a juvenile; 2. Delayed reattachment of retina after operation on an aphakic eye; 3. Orbital hemangiectasia with marked proptosis; Removal with preservation of vision.

H. Rommel Hildreth,
Editor.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

May 24, 1938

DR. J. HARLEY HARRIS, *presiding*

FOREIGN BODY IN THE EYE

DR. E. C. ELLETT reported the case of Mr. E. D. M., aged 37 years, who was first examined on February 25, 1938.

On October 1, 1937, while at work driving a steel pin with a steel punch something struck the right eye. He received medical attention but no X-ray studies were made. The vision of the right eye was 5/10. The eye was slightly red. Tension was normal; the fundus appeared normal except for a few vitreous floaters. There was a small scar at the nasal edge of the cornea and under this a hole in the iris, seen by transillumination only. The X-ray film showed a foreign body in the right eye, 1 by 1 mm., 5 mm. below the horizontal, 0.5 mm. to the temporal side and 6 mm. behind the cornea. No trace of it could be seen with the ophthalmoscope or slitlamp.

The large magnet pulled the foreign body around the lens. It was drawn free of the iris and removed by a keratome incision upward without iridectomy. A silver spatula was passed into the anterior chamber and the foreign body was slid out along it, the spatula protecting the iris.

The patient went back to work April 18, 1938. Except for a small defect in the iris, down and another one in, and a few fine vitreous opacities, the eye is normal. Vision of the right eye is 5/4—2 and J1.

SYMBLEPHARON

DR. PHIL M. LEWIS presented a white man, 65 years of age, upon whom he had recently operated for a symblepharon of the lower lid, consequent upon a burn of the right eye 20 years previously. The adhesion extended from the lower fornix to the upper border of the pupillary space. Vision was reduced to the counting of fingers. The eye had been previously operated on in another city a year or two after the accident, but no improvement followed. Motion of the eye was very limited.

On April 21, 1938, the operation was

performed. The growth was dissected from the cornea and sutured to the inner surface of the lower lid so as partially to line the raw surface. The conjunctiva was dissected up from each side but was found insufficient to cover the defect. Mucous-membrane grafts were cut from the lip and used to cover the raw area on the eyeball and the inner surface of the lid.

The vision is now greatly improved, but considerable corneal opacity remains. The lid is entirely free from the eyeball, so that motion of the eye is normal.

MALIGNANT MELANOMA—SUBSEQUENT DEATH FROM METASTATIC CARCINOMA

DR. PHIL M. LEWIS reported a case of considerable interest which he had followed for a number of years. The patient was first examined in March, 1928, at the age of 57 years, because of headache following reading or sewing. She had a fairly high hyperopia with a small amount of astigmatism. Correction of this gave a vision of 20/20+ in each eye. The fundi were normal except for a moderate degree of sclerosis of the retinal vessels. In August, 1929, she returned complaining of headache and a burning of her eyes. Vision was found to be normal and her glasses required no change. The retinal vessels showed considerable sclerosis, and on taking her blood pressure it was found to be well over 200. She was referred to her physician for treatment.

In May, 1931, she returned complaining that her vision was failing, especially for close range. Proper correction gave normal vision for distance and for near. Seven months later, in December, 1931, she returned because the vision of her right eye was getting very poor. Examination revealed a bullous retinal detachment of the upper, inner quadrant. No tear was found. Tension was 23 mm.;

transillumination was negative. A Gonin ignipuncture was performed and while some improvement was noticed temporarily, the vision soon became worse, and the detachment more extensive. This process continued through 1932 and 1933.

In March, 1934, the eye was found to be completely blind, and she stated that it had been blind for several months. The retina was completely detached and tension was normal to fingers. The eye was not transilluminated as no thought was given to the possibility of an intraocular tumor. In November, 1934, she came in reporting redness, swelling, and pain for the past two days. The eye was found to be very hard, the tension being 70 mm. (Schiotz). Transillumination was good below and nasally, which included the area involved by the original detachment. The upper outer quadrant failed to transilluminate. Enucleation was performed a few days later and a glass ball was implanted.

The eye was sent to the Army Medical Museum at Washington, and Lt. Col. George R. Callendar reported it to contain a malignant melanoma. No X-ray therapy was given. The patient was seen several times during 1935, 1936, and 1937. No recurrence was ever noticed.

In September, 1934, the patient had a panhysterectomy, but the uterine tumor which was present was found to be a myoma. Three years later she was found to have a squamous-cell carcinoma of the vagina which was quite extensive and could not be entirely removed. She was at that time 67 years of age and in bad general condition, having a severe arteriosclerosis with hypertension. She died in March, 1938, of a generalized carcinomatosis. There was no evidence of a tumor in the orbit.

RETINOBLASTOMA WITH METASTASIS

DR. J. WESLEY MCKINNEY reported

the case of A. H., aged five years, whose left eye had been enucleated 13 months ago on account of retinoblastoma. The tumor had shown early invasion of the optic nerve, but the nerve had been sectioned well behind the growth.

One month ago the mother noticed on the right shoulder blade a knot which has gradually enlarged. X-ray showed widespread erosion of the scapula. Examination of the socket showed no evidence of local recurrence and with dilated pupil there was no sign of tumor in the other eye. A biopsy was taken from the scapula tumor. The pathologist reported the tumor to be made up of cells identical with those in the ocular tumor. The tumor is at present being treated with X-ray therapy.

The question arose as to whether this might not be a Ewing's tumor, but it was the consensus of the pathologists who examined the slides that, although the microscopic picture did resemble Ewing's tumor, this was a metastatic retinoblastoma. In the latter case it is certainly unusual that a retinoblastoma should metastasize after one year without local recurrence.

Discussion. Dr. E. C. Ellett recalled only one similar case in which the eye was removed for retinoblastoma and about a year later a mass was found on the left ulna which was diagnosed Ewing's tumor.

J. Wesley McKinney,
Secretary.

OXFORD OPHTHALMOLOGICAL CONGRESS

The Oxford Congress for 1938 was held July 7, 8, and 9. On July 16 the *Lancet* published a good account of the Congress. This contrasts strongly with the usual neglect shown by general medical journals to scientific meetings dealing

with diseases of the eye. The proceedings of this Congress in full will be published in the Transactions of the Ophthalmological Society of the United Kingdom, some time in 1939.

OCULAR PALSIES

PROF. CAIRNS, of Oxford, reported that ocular palsies result chiefly from pressure, or stretching of the nerves in the cranium or in the orbit. Their clinical manifestations depend on the progress of the causative lesions. Orbital abscess paralyzes all the external ocular muscles, partly or completely. Evacuation of the abscess brings prompt recovery. Benign tumors of the orbit disturb the ocular movements but little. Palsies are often the first noticed symptoms of malignant tumors. Metastatic tumors of the roof of the orbit cause diplopia with pain. Ophthalmoplegia with exophthalmos may follow thyroidectomy, or may develop without thyroid disease. Such palsies may arise from carotid aneurysm, tumors of the middle fossa, cyst of a sphenoidal sinus, cranial polyneuritis, tumor of the Gasserian ganglion, or lipid deposits in the bones of the skull. These cases must be studied by modern methods, including radiography of the bones, ventricles, and arteries.

CATARACT

PROF. A. VON SZILY, former Director of the Eye Clinic of Münster, Germany, gave the Doyne Lecture. He took up the pathological examinations and morphologic findings, and the contributions of embryology, biomicroscopy, and biochemistry to our changing views about the lens. Histological slides showed displacement of the nuclear corona, and other features of abnormal development. He traced the development of punctate, lamellar, and nuclear cataracts. Calcium deposits are the most common of chemi-

cal changes in cataract. Cholesterin crystals are found less often. Lack of vitamin C influences the production of cataracts. Lens tissue is especially sensitive to intermediate products of metabolism.

CONTACT GLASSES

MR. F. A. WILLIAMSON-NOBLE, of London, said only recently had it been possible to produce contact glasses that could be worn with comfort by many people. The indications for contact glasses were optical, occupational, and cosmetic. Conical cornea, high myopia, after effects of mustard-gas burns, nebulas and facets of the cornea, any surface irregularity in the pupillary area of the cornea, may produce interference with vision that cannot be remedied by ordinary glasses. But the filling in, by saline fluid, of the space between the cornea and the glass, could produce great improvement of vision. Some patients reported discomfort during the first hour of wearing them; after which they became progressively more comfortable. Of myopic patients tested, 60 percent could wear contact glasses for six hours or more.

INTRACRANIAL AND INTRAOCULAR PRESSURE

PROF. HANS LAUBER, formerly of Vienna, now of Warsaw, spoke on the relation between intracranial and retinal blood pressure and intracranial tension. The relation between retinal venous and arterial pressure varies between 1 to 1.8 and 1 to 3. So long as this normal relation is preserved no papilledema occurs, in spite of high arterial pressure. He described the influence of low arterial pressure in accelerating the progress of optic-nerve atrophy. He pointed out that the circulation in the retina, differs from that in the tissues because the intraocular tension acts on the vessels, especially on the capillaries. If the difference between

diastolic blood pressure in the retinal arteries and the intraocular pressure is less than 20 mm., nutrition of the retina is impaired; especially the oxygen supply is insufficient. This is illustrated in glaucoma and in tabetic optic atrophy, Leber's disease, and retinitis pigmentosa, in which low blood pressure is often found. In such conditions the arterial pressure should be raised and the intraocular pressure kept down by pilocarpine, or by cyclodialysis.

PAPILLEDEMA

DR. VAN HEUVEN, of Utrecht, had checked the relations between venous pulsation seen with the ophthalmoscope and intracranial pressure, and found lack of venous pulsation to be an important sign of early papilledema. The colloid chemical conditions of the optic nerve and surrounding tissues also influence the development of papilledema. He referred to Prof. Lauber's observation that compression of the vein, but not of the artery, causes rapid development of papilledema.

ANESTHESIA OF OPHTHALMIC SURGERY

MR. H. M. TRAQUAIR, of Edinburgh, opened a discussion of this subject. He reviewed the development of the technique for securing local anesthesia for eye work. Total anesthesia has now been achieved by injections around the lids, applying cocaine to the eye, and subconjunctival injections above and below the cornea.

GLAUCOMA

MR. HARRISON-BUTLER illustrated detachment of the zonular lamellae of the lens, in what he called capsular glaucoma. Otto Barkan, of San Francisco, found that the angle of the anterior chamber was often blocked in glaucoma,

and that shreds of capsule might often be found there. Mr. Ridley, of London, called attention to a substance in the tears similar to histamine. It caused a rise of intraocular pressure, through vascular dilatation.

MINNESOTA ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

SECTION ON OPHTHALMOLOGY

March 11, 1938

DR. WALTER CAMP, *president*

HEADACHES OF OCULAR ORIGIN

DR. A. D. RUEDEMANN of Cleveland gave a talk on this subject.

Discussion. Dr. A. D. Prangen said it is important to see that the patient has a thorough physical, and possibly a neurological, examination in a search for all the possible factors which might be causing the headaches. In cases of chronic headache of doubtful origin it seems best that some one consultant be made a sort of clearing house for all the clinical data and that he make an attempt to put the various component parts of the clinical picture together in an attempt to establish a diagnosis.

Dr. A. D. Ruedemann in answering Dr. Fink regarding children and their headaches said the child himself must be considered. He may belong to a social group in which headaches are common or he may come from more or less inferior stock. Such a child comes in contact with normal individuals and is expected by his parents to carry on as a normal child. We must remember that headache is foreign to the child as he starts out in life and someone must impart to him the idea of headache.

George E. McGeary,
Secretary.

Directors: EDWARD JACKSON, President, LAWRENCE T. POST, Vice-President, DR. F. E. WOODRUFF, Secretary and Treasurer, WILLIAM L. BENEDICT, WILLIAM H. CRISP, HARRY S. GRADLE.

Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to *Dr. Lawrence T. Post, 640 S. Kingshighway, Saint Louis.*

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver.*

Subscriptions, applications for single copies, notices of change of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 640 S. Kingshighway, Saint Louis.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceeding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

PLASTIC SURGERY OF THE EYES

The eye is the feature most observed in the face. Its perfection in appearance, movement, and expression, is most important to the pride, self confidence, and economic and social well-being of its possessor. The cosmetic effect must be thought of in connection with every plastic operation, considered and advised to be done on the eye, or the parts visibly related to it. The danger of untoward cosmetic results may influence the conscientious surgeon to avoid doing or advising operation. Even a squint operation or a cataract extraction may have unpleasant cosmetic sequels for both surgeon and patient.

When an operation should be done to

correct a cosmetic defect from injury, poor repair, cicatricial deformity of trauma, or disease, the ophthalmologist may feel lack of experience in just that kind of operation, so that he hesitates to do it or advise it—although apart from his interest in the patient's welfare, and his own reputation, he may feel that something of the kind is clearly indicated and might properly be done.

The plastic surgery of the eye is likely to be a specialty within the specialty. The surgeon who has had large experience in ophthalmic surgery knows how easily operative results may be disappointing and feels he is in more danger of blame for what he has done than for what he has left undone. He is not likely to begin doing operations of this kind in the hope

of developing skill that will justify his efforts and risks. Plastic operations are more likely to be undertaken by young operators who have seen successful results in the practice of their teachers and who feel they have had the preparation to meet the difficulties and obstacles that beset plastic surgery.

Those who have seen the work and the results achieved in this field by John M. Wheeler, will feel that his untimely death was indeed an irreparable loss. His developed judgment and manual dexterity as well as his large experience gave him a fitness for this work that very few can hope to attain. Nevertheless such work must be done, and it is to the interest of all ophthalmologists that it be done in the most expert manner.

To be fitted for plastic surgery of the eye, one must have a clear and fresh knowledge of the minute anatomy and physiology of the eye and adjoining structures. An operation always changes somewhat the relations of the parts involved, and may so change the nerve and vascular supply as to impair cell life. The skin, mucous membrane, cilia, tarsal tissues, movements of the lids and eyeballs, even the tissues of the nose, and the walls of the orbit, must be considered in plastic surgery, both with regard to their normal anatomy and their physiologic processes of repair. Corneal replacement by grafting is a new branch of plastic surgery. Glaucoma still presents unsolved surgical problems. The nutrition of the transparent tissues of the eye is different from that of all other animal tissues, in ways not well understood.

The maintenance of the curves of the dioptric surfaces and their relation to the retina is a necessary condition of good vision. How these relations are maintained is imperfectly understood. So that any operation on the eyeball is a venture in the dark. The cosmetic effects of oph-

thalmic operations are too important to be ignored, and too uncertain to be disregarded. The updrawn pupil of intracapsular cataract extraction, should give us pause until it is better understood. Cosmetic effects may be thought unimportant; but their implications may be serious. Plastic surgery seeks to improve the condition of living tissues. The experience of the surgeon who does it is of high importance to the ophthalmologist.

Edward Jackson.

CONJUNCTIVAL PEMPHIGUS

There are probably many ophthalmologists who have never seen a case of conjunctival pemphigus. The condition is rare even in the clinic. Textbooks have little to say about it, the statement being usually limited to a brief description of its essentially atrophic character, with some allusion to rarity, obscurity, and hopelessness.

Essential shrinking of the conjunctiva has been classed as a closely related condition, if not actually identical with pemphigus. Both disturbances tend gradually, sometimes in the course of many years, to contraction of the conjunctival sac, formation of adhesions between conjunctiva and cornea, and serious loss of vision. The distinction between the two, so far as any difference certainly exists, lies in the fact that the lesions of conjunctival pemphigus are more or less generally regarded as beginning with the formation of blebs, whose rupture is followed by development of scar tissue. A number of writers, however, have suggested that such blebs probably existed in the cases of essential shrinking but escaped notice on account of the slow and insidious course of the disease.

As regards the general skin and mucous-membrane surfaces of the body the term "pemphigus vulgaris" is applied by der-

matologists to a disorder accompanied by blebs on the skin or mucous membrane. Its differentiation from herpes, urticaria, eczema, drug eruptions, and so on is more or less difficult but depends to some extent upon an exaggerated tendency of pemphigus blebs to break down, leaving moist defects, which in the more severe types are followed by deep inflammation, tissue destruction, and scar formation.

As bearing upon the question of identity between pemphigus and essential shrinking of the conjunctiva, Franke, who assembled 107 cases from the literature, found that one tenth of the cases of essential shrinking had a record of pemphigus in another part of the body.

The appearances encountered in ocular pemphigus are manifestly influenced by local anatomic and secretory conditions. The constant flow of tears, and the movements of the lids and globe, favor maceration and probably increase the liability to secondary infection and the formation of granulation tissue. Symblepharon arises from adhesion between two superimposed areas of erosion.

The few attempts made to explain the nature and causation of this destructive process must be described as unsuccessful. Intestinal toxins and endocrine or general nervous derangement have been incriminated, and more recently there has been some disposition to attribute the disease to a living virus. The fact that conjunctival scrapings, and also the contents of the epithelial blebs, show eosinophilia has been thought to suggest an allergic basis.

A careful analysis of the pathologic processes involved is offered by Meyer (*Klinische Monatsblätter für Augenheilkunde*, 1938, volume 101, page 708), his material being two cases seen at the Freiburg clinic and an old specimen from the Axenfeld collection. In the first clinical case, under observation for thirteen years,

there had for ten years been some doubt as to the diagnosis. In the second patient, in the course of "essential shrinking of the conjunctiva," there were bleb formations on the mucous membrane of the palate and larynx, and the skin also became involved.

The old excised piece of conjunctiva which Meyer was able to study showed a chronic inflammatory process, with development of abundance of young connective tissue. The epithelium had completely lost its mucous character, and there were no goblet cells. There was some evidence in favor of Kreibich's view that the pemphigus bleb develops on the basis of preëxisting inflammation.

In common with reported cases of pemphigus foliaceus of the skin, the specimen showed flat epithelial elevations (rather horizontal gaps than blebs), lamellar exfoliation, marked infiltration of the cutis with round cells, thickening of the epithelial layer, granulation and proliferation, and secondary cicatricial shrinkage.

In the first of the two clinical cases, severe exacerbations alternated with remissions of as much as several months during which no discomfort was experienced. Definite bleb formation was encountered only once in the whole course of the disease, but denuded areas, frequently seen, were regarded as representing the remains of very fugitive blebs.

In the second patient, a man 82 years old, the existence of the condition could be traced back for only two years. The case was a typical one of essential shrinking of the conjunctiva, without any suggestion of bleb formation. As to both conjunctiva and skin, the process was of the malignant and persistent type involving the deeper layers. Although tubercles were encountered in the affected tissue, with epithelioid and giant cells, central necrosis, and infiltration by lymphocytes.

attempts to demonstrate tubercle-bacillus infection were entirely unsuccessful and there was no clinical evidence pointing to such an etiology. In place of bleb formation the epithelium displayed a pronounced tendency to exfoliation.

In attempting palliative treatment of conjunctival pemphigus, one must not be misled by the spontaneous remissions, which may last sometimes for years. One exception only seems possible to the general statement that treatment is practically useless. In the former of the two clinical cases described by Meyer, four plastic operations were successfully performed for the relief of trichiasis and entropion. These operations arrested corneal ulcers which had been induced by the trichiasis, although (it is interesting to observe) there was subsequently distinct evidence of bleb formation on the healed transplants. This is an excellent illustration of the fact that surgical ingenuity may often prove beneficial even in fundamentally incurable conditions.

W. H. Crisp.

GIZA LABORATORY REPORT

This twelfth annual volume for 1937 is similar to its predecessors and of like excellence. The group forms an interesting and valuable collection. It is unfortunate that more organizations cannot publish similar reports. The major difficulty lies in the expense of the project.

Many interesting pathological and clinical cases are given; among them is one of bilateral multinodular episcleritis, supposedly tuberculous, which was cured by tuberculin injections. Two cases of Eales's disease in brothers are reported.

The research section, is as usual, excellent. The work on trachoma has been continued. Giza is undoubtedly one of the most important centers in the world for this study, and anything emanating there-

from must be given serious consideration.

Among the sections that will catch the eye of the reviewer is the experience with sulfanilamide chemotherapy in trachoma. Ten children with active trachoma and pannus—but not secondarily infected—were treated as outlined by the United States Public Health Service. The drug appeared to have no effect on the disease. This is in line with the findings of many observers in the United States. Though there is a truly remarkable improvement in cases of trachoma which have been secondarily infected, the sulfanilamide having cleared up the secondary infection there does not seem to have been much good done for the disease itself.

The uselessness of extract of adrenal cortex in chronic simple glaucoma was demonstrated as anticipated in a small series of cases.

The section on spring catarrh is especially interesting and well done. It is beautifully illustrated in black and white and in colors. The mechanics underlying the various appearances are clearly explained; anatomical arrangements seemingly lie at the basis of these. A capillary leakage with collection of exudate and then absorption more or less paralleling it take place. The picture differs in different regions because of the varying anatomy. In the palpebral type the epithelium is exhausted because the leakage is too rapid for all of it to be successfully passed through the epithelium. Broad papillae are formed which gradually become vascularized, and the characteristic "cobble stones" are formed. The unreliability of trusting to the finding of eosinophilic cells as a differential point, at least in Egypt, is again brought out. In from 60 to 70 percent of hospital patients eosinophiles were found in the conjunctival secretion. This may be due to the prevalence of intestinal parasites in the native population. The better test suggested is that the pal-

pebral conjunctiva be dried and exposed to the air for a few minutes, following which a thin glistening tenacious membrane will form in cases of vernal catarrh.

Many cases have been studied and the author presents a very convincing thesis. The reader cannot fail to want to confirm these slitlamp findings in his own patients.

These Reports are well prepared, valuable, and should have a wide circulation.

Lawrence T. Post.

BOOK NOTICES

AMERICAN RECOMMENDED PRACTICE OF SCHOOL LIGHTING. American Standards Association, New York. Paper bound, 60 pages, 39 illustrations, 1938. Price 25 cents.

The practice recommended in this pamphlet may not be ideal but it is decidedly an advance on the lighting now used in the great majority of schools. A single illustration in it, showing the difference between indoor daylight and that which we live in out-of-doors, will be worth more than the price to any one who thinks about the health of children, or the need for good light in schools. The book has been prepared under the joint sponsorship of the Illuminating Engineering Society of New York and the American Institute of Architects of Washington, D.C. It is arranged in four parts: 1. Lighting and education. 2. Factors which affect lighting and seeing. 3. Natural lighting of schoolrooms. 4. Artificial lighting of school rooms. The last part occupies more space than the other three and has more than five sixths of the illustrations. This, and the fact that a Part 5 (three pages) is devoted to Wiring, may give the impression that the book is simply intended to serve the interests of those who sell electric power and fixtures. But in spite of this, it should be known to all

who are interested in the vision and health of school children.

The one illustration above alluded to, shows, on one page, reproductions of three photographs: one of a playground at noon taken by 10,000 foot-candles of daylight; the second a group of school children outdoors in light ranging from 450 to 700 foot-candles; the third taken in the school-room by natural light, in which the illumination ranged from 240 foot-candles in the window, to 8 foot-candles on the desks at the opposite side of the room. Architects have made such poor use of natural daylight that some provision of artificial light is needed in almost every schoolroom.

It is encouraging to find that the part on "Natural lighting of schoolrooms" begins with a discussion of "orientation of building." Architects have heretofore been given the impossible task of providing for natural lighting in buildings from which daylight was shut off by trees and higher buildings around them. In these days when, in the heart of large cities, high and costly buildings are being torn down to provide parking spaces, because that use would give the best return to the owners of the ground, it should be possible for any school board, holding the ideal of a balanced budget, to provide for natural light by surrounding each school building with parking spaces. The future growing appreciation of the child's need for light and physical development, will bring an understanding to school boards and tax payers that every school should be surrounded by playgrounds. The regular exercises, using the proper apparatus and games for the different grades of children, will increase the value and efficiency of the school more than anything that can be put into the indoor school curriculum.

Every ophthalmologist can profitably read and consider the things set forth in

this book. It will give him new light on the importance of exact correction of errors of refraction, and the balance of ocular movements. The traditions and history of operative ophthalmology, and the importance of hospitals and asepsis, newly discovered, overshadow and obscure the supreme importance of visual function in our present civilization.

Edward Jackson.

BULLETINS ET MEMOIRES DE LA SOCIÉTÉ FRANÇAISE D'OPHTHALMOLOGIE. Volume 51. 647 pages. Paris, Masson et Cie, 1938.

This annual volume records the presentations made during the meetings held May 16-19, 1938. A total of 43 communications was offered, and they cover a number of different subjects, although the majority are devoted to therapeutic and surgical methods in use for various ocular manifestations. While certain reports will have special appeal for different readers, the volume forms *in toto* an interesting and readable collection. Because of the number and diversity of the individual papers, it is difficult to render them into adequate résumés. The meeting of

May 18th was devoted to what might be termed a symposium on cataract, eight different reports being given over to this subject.

It is particularly gratifying to see the adaptation to ophthalmological problems of newer experimental procedures developed in other fields. Thus, a paper by Tillé, Pillet, and Busnel on micro-incineration and tissue spectography presents a new approach to the problem of cataract formation. These newer methods reveal, for example, that while normal crystalline and the amber senile cataract contain neither iron, copper, nor zinc, the white senile cataract contains only copper, and the black cataracts of either spontaneous or traumatic origin contain both copper and iron.

L. A. Julianelle.

GIZA MEMORIAL OPHTHALMIC LABORATORY, Twelfth Annual Report, 1937. Paperbound, 168 pages, 67 illustrations, some in color. Printed by Schindler's Press, Cairo, 1938. Price P.T. 35.

See editorial "Giza Laboratory report," page 443.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is only mentioned in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Busigin, H. V. Another type of ophthalmoscope. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 523.

The author has designed an ophthalmoscope attached to a headband, thus leaving the hands free.

Ray K. Daily.

Goldman, Hans. The technique of slitlamp microscopy. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Nov., p. 90.

The author describes accessories to the slitlamp that simplify several complex procedures. For examination of the fundus, he places a prism in the path of the beam after it leaves the distal lens. By double reflection from two of the surfaces of the prism, the angle between the axis of illumination and of observation is reduced to 5°. When the patient wears a very light contact glass made of a glass substitute, the fundus and the posterior parts of the vitreous can be conveniently examined. For

gonioscopy of the entire chamber angle with the patient seated at the slitlamp, the author has devised a similar light contact-glass. Its anterior surface is flat and it has embedded in it a totally reflecting plane surface which lies at an angle of 64° with the anterior plane. By rotating the glass about its axis all parts of the chamber angle can be brought successively into view. For illumination, the slitlamp is used with the special deflecting prism.

F. Herbert Haessler.

Streiff, E. B. Adaptation of the Nordenson apparatus to keratoscopy and to photography of the anterior segment of the eye. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Nov., p. 84.

By replacing the +0.75 D. lens in the Recross disc with a +2.25 D. lens, very acceptable photographs of the lids and the anterior segment of the eyeball may be made. By putting a +16.00 D. lens in place of the color filter, vitreous opacities may be photographed. A

translucent Placido disc, 40 cm. in diameter, with four lamps behind it mounted on the distal end of the horizontal tube, converts the instrument into an adequate photokeratoscope.

F. Herbert Haessler.

Viallefont and Lafon. **Entopic pupillometry; spontaneous variations of the pupillary diameter.** Bull. Soc. Franç. d'Opht., 1938, v. 51, pp. 378-381. (See Amer. Jour. Ophth., 1939, v. 22, Feb., p. 226.)

Zamenhof, Adam. **A small illuminator for campimetry.** Klinika Oczna, 1938, v. 16, pt. 5, 592.

The author describes a handlight which projects a circle of light on the campimetric screen. (Illustration.)

Ray K. Daily

2

THERAPEUTICS AND OPERATIONS

Allen, J. H., and Braley A. E. **Staphylococcus toxin.** Amer. Jour. Ophth., 1939, v. 22, Jan., pp. 11-15.

Glover, L. P. **Some uses of sulphanilamide in ophthalmology.** Amer. Jour. Ophth., 1939, v. 22, Feb., pp. 180-184.

Goar, E. L. **Management of the complications of intraocular surgery.** Amer. Jour. Surg., 1938, v. 42, Oct., pp. 62-68.

A discussion of prevention and treatment of the complications of intraocular surgery. Goar prefers iridencleisis to trephining in glaucoma and gives his technique. (3 references.)

Ralph W. Danielson.

Green, J. **The conjunctival flap in ophthalmic surgery.** Amer. Jour. Surg., 1938, v. 42, Oct., pp. 69-77.

Green discusses the use of the conjunctival flap not only in removal of cataracts but also in the following: (1)

rupture of wound after extraction of lens, (2) various complications of trephine operations, (3) keratoplasty, (4) progressive ulceration of the cornea, (5) for covering a shrunken, blind eye to make a bed for prothesis, (6) gonorrheal ophthalmia, to prevent ulceration of the cornea. (21 references.)

Ralph W. Danielson.

Jacqueau, M. **Very long and extensive use of shock medication by intravenous injections of electrauro.** Bull. Soc. Franç. d'Opht., 1938, v. 51, pp. 273-277.

For eighteen years the author has used electrauro intravenously as a means of shock therapy, to the exclusion of all other methods. He estimates that a total of 3,000 injections have been administered. The usual dose was 3 c.c. The indications for use are disturbances following cataract operations, iritis with hypopyon, late intraocular infection following sclerectomy, traumatic perforation of the globe, sympathetic ophthalmia, and infectious or inflammatory states generally.

Clarence W. Rainey.

Kapuscinski, W. J. **Typhoid vaccine in ocular therapeutics.** Bull. Soc. Franç. d'Opht., 1938, v. 51, pp. 277-293.

The author considers that typhoid vaccine acts chiefly by the increased temperature that it produces, and considers it in the same category with hyperthermia induced by other means. He uses a vaccine prepared by the Institute of Hygiene of Warsaw, which has a uniform and constant bacterial count of 1 billion per c.c. The initial dose of 0.01 c.c. is given intravenously. If the temperature does not rise above 39°C., a second dose of 0.03 c.c. is given the day following fall of the temperature induced by the first dose.

Usually a temperature of 40°C., is obtained within four to six hours after the second injection. The injections are given in a series of ten to twelve. A fever of 40°C. should follow each injection. If the patient is not sensitive to the injection the dose is doubled for the following injection. If the patient is oversensitive to the injection, the dose is reduced by a third. The injections are made in the morning, the peak of the temperature rise occurs in the early afternoon, and by evening the patient has a normal temperature. The author reports his results in treating cases of sympathetic ophthalmia, interstitial keratitis, herpes zoster of the cornea, gonococcal conjunctivitis, juvenile recurrent hemorrhage into the vitreous, and retrobulbar neuritis. For tuberculous uveitis, he prefers typhoid vaccine to the use of tuberculin.

Clarence W. Rainey.

Karbowski, M. Iontophoresis with adrenalin in ocular therapeutics. *Acta Ophth. Orientalia*, 1938, v. 1, Oct., p. 9.

Iontophoresis is, according to the author, an easily applicable and harmless method of treatment, and should be used to a greater extent in ophthalmology, especially since it opens new ways of treatment of the anterior and posterior segments of the uvea, the retina, and, perhaps, the lens and vitreous. Adrenalin iontophoresis, while it is as effective as subconjunctival injection, has the additional advantage of not affecting the general circulation.

R. Grunfeld.

Laval, Joseph. Vitamin therapy in ophthalmic practice. *Amer. Jour. Ophth.*, 1939, v. 22, Jan., pp. 33-37.

Lemoine, A. N. Hyperpyrexia in the treatment of ocular syphilis. *Arch. of*

Physical Therapy, 1938, v. 19, Nov., p. 675.

Cases of syphilitic interstitial keratitis, optic neuritis, secondary optic atrophy, primary optic atrophy, and chorioretinitis were treated by hyperpyrexia, induced either by tertian malaria or the hot bath. Results obtained by the use of the hot bath were as good, though not so rapid, as those obtained by malarial parasites. Clearing of salmon patches and corneal opacities in interstitial keratitis, and subsidence of the acute reaction in neuroretinitis, were considered to be more rapid than in other forms of treatment. Primary optic atrophy seemed to be arrested, and vision and fields improved in some instances.

George A. Filmer.

Spaeth, E. B. A review of some modern methods for ophthalmic plastic surgery. *Amer. Jour. Surg.*, 1938, v. 42, Oct., pp. 89-100.

The author appreciates that most of the contents have been published before in various texts and monographs, and also that considerable important detail is not here included. The article is, however, presented as a convenient abstract of some of the principles which underlie ophthalmic plastic surgery.

Ralph W. Danielson.

3

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Berner, G. E., and Berner, D. E. Reading difficulties in children. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 829-838.

The modern method of teaching reading by sentences, while it produces rapid and intelligent readers, taxes to the limit the child's powers of attention and concentration. Because of the high degree of visual attention re-

quired, certain minor defects of less importance under older methods have now become significant. Besides gross visual defects, the factors responsible for most reading difficulties are: visual immaturity, low hyperopia, deficient fusion, and deficient fusional convergence. The authors discuss these factors and point out methods of correcting them.

J. Hewitt Judd.

Bettman, J. W., and McNair, G. S. A contact-lens telescopic system. *Amer. Jour. Ophth.*, 1939, v. 22, Jan., pp. 27-33.

Bietti, Giambattista. Researches on the mechanism of action of sympathotrope substances on the light sense. *Boll. d'Ocul.*, 1938, v. 17, April, pp. 279-306.

Different persons having normal eyes or affected by retinitis pigmentosa were tested to find out how their light sense was affected by sympathetic-stimulant drugs such as adrenalin and sympathetic-paralyzing drugs such as lymphoganglin and ergotamin. The conclusions are given in tabulated form. Conjunctival instillation of the first group of drugs is followed by deterioration of light sense. Improvement accompanies the action of the other group of drugs.

The first group of drugs, subcutaneously administered, it is not usually followed by deterioration of light sense, but sometimes even by improvement. Experiments on frogs indicated that the first group of drugs caused, in retina kept in the dark, migration of retinal pigment along the rods and cones toward the external limiting membrane in the "light" position. The second group of drugs, on the other hand, tended to cause migration of the pigment exposed to light toward the

pigmented epithelium, that is, the "dark" position. The experiments with adrenalin showed, however, that the improvement of the light sense was only partly due to migration of the retinal pigment, and that a notable part was played by the vascular factor. Injections of the adrenalin group were followed by vasodilatation in the region of the central artery of the retina, and this mechanism is taken to explain the improvement of light sense obtained with such medicaments after subcutaneous injection.

Melchior Lombardo.

De' Cori, Renzo. Sphygmie oscillations of corneal curvature. *Boll. d'Ocul.*, 1938, v. 17, March, pp. 153-162.

The right eye of a woman of eighteen years was found with the exophthalmometer 1 mm. more prominent than the left eye and to be affected by compound direct myopic astigmatism. During examination with the ophthalmometer the cornea of this eye showed rhythmic changes, its horizontal curve varying from 55 to 55.25 D. and the vertical from 58.5 to 59.25 D.; that is, the radius of the horizontal meridian was shortened from 6.1 to 6.07 mm. and the vertical from 5.75 to 5.68 mm. These changes were synchronous with the pulse, the maximal value appearing during systole, when the astigmatism increased 0.5 D. The article closes with a discussion of probable factors. (Bibliography.) Melchior Lombardo.

Eames, T. H. The speed of picture recognition and the speed of word recognition in cases of reading difficulty. *Amer. Jour. Ophth.*, 1938, v. 21, Dec., pp. 1370-1375.

Essen, Jac. The quality of darkness. (Answer to Ohm.) *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 817-838.

Essen answers that Ohm could not have understood his original paper, since Ohm insists that darkness is objectively the absence of light (see p. 453.) Essen explains that he is an investigator in psychology, occupied with the principles of sensory perception and experience in sight and hearing. He is also occupied in physiologic research. Obscurity or darkness is not of a physical nature but an optical sensory perception and is not the opposite of brightness but of the optical sensory perception of clearness. Obscurity or darkness is an absolutely photic experience in which the aphotic factor or the perception of black prevails. Lack of optical differentiation signifies both failure to perceive visible objects in the visual field and exclusion from the real world of sensory experiences. The phenomenon of blindness is psychologically as well as physiologically associated in the narrowest sense with that of obscurity or darkness. Blindness is the particular experienced form of obscurity or darkness.

H. D. Lamb.

Granit, R., Holmberg, T., and Zewi, M. On the mode of action of visual purple on the rod cell. *Jour. of Physiology*, 1938, v. 94, Dec., p. 430.

Measurements were undertaken in dark-adapted eyes of frogs to determine the relationship between the size of the retinal electrical response and the total quantity of visual purple present when the eyes were subjected to a constant test light of wave length 0.500 micra. It was found that the quantity of visual purple in these eyes remained the same as in control eyes, although the retinal electrical response was reduced one third to one half by adaptation. These results were particularly interesting in view of the fact that the retinal electri-

cal response is known to increase during regeneration of visual purple. The authors suggest a hypothesis to account for the apparent discrepancy.

George A. Filmer.

Hawes, R. T. M. Notes on dark adaptation and a single instrument for its investigation. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 103.

The author describes an instrument which he has devised as an attempt to eliminate certain inherent errors in some of the previous instruments for determination of dark adaptation. The tube is completely illuminated, so that the whole retina is bathed in light during the bleaching period. The test object is an arrow which can be moved in any direction without the knowledge of the observer and the illumination is controlled by polaroid discs so that definite percentage and very smooth diminution in the light illuminating the arrow are possible.

Three series of experiments are summarized; (1) as to the number who saw the arrow illuminated by 60 percent of the available light at varying times after the bleaching light was extinguished; (2) for determining whether familiarity with the instrument altered the findings; and (3) the effects of administration of vitamin A in halibut-liver oil on eleven of the worst subjects.

Beulah Cushman.

Karbowski M. The pathology of color perception. *Graefes Arch.*, 1938, v. 139, pt. 3, p. 480-502.

The disturbances of normal perception of color located in the eye are divided into those due to opacities in cornea, lens, anterior chamber, and vitreous and those due to changes in the function of the retinal cones. Any

diminution in the transparency of the ocular media causes exclusion of the rays at the blue end of the spectrum. Changes in the function of the cone include paresis, paralysis, or spastic contraction of the myoid in the inner portion of the cone. In both instances, only one platelet in the outer portion of the cone, corresponding to a single color, can under such conditions come into the focus of the light rays. Thus the erythroptia and red and green blindness of the snow-blind are explained. Nutritional disturbances or toxic influences may influence color vision by changing the absorptive capacity of the color-sensitive cone and the ability of the physical stimulus to change to nervous energy. A smaller part of the blood supply to the cones comes from the retinal blood vessels. Accordingly, in all forms of choroiditis, choroidal tumor, choroidal tear, choroidal detachment, retinal detachment, and myopia, the violet and blue rays perceived by the platelets at the tip of the cone are first affected, whereas the red and orange rays perceived by the platelets at the base of the outer part of the cone are less disturbed. In addition, the fact that blue is also poorly distinguished in degenerative disorders of the retina, such as hypertonic, nephritic, diabetic, tuberculous, and syphilitic retinitis, together with pigmentary degenerations of the retina, would indicate that in all these conditions the etiologic factor comes from the choroid. On the other hand, when the nutrition from retinal blood vessels is concerned, recognition of red is first disturbed. This would occur in early inflammatory and degenerative processes of the second and third neurons of the retina. The primary cause might be spasm or embolus of the retinal arteries, passive hyperemia, or thrombosis of the retinal

veins. It could be an early differential symptom in multiple sclerosis, pituitary tumor, or retrobulbar neuritis but is also present in optic atrophy from glaucoma, from embolus of the central retinal artery, and from tabes. Changes in the visual fields for red may be either contraction, quadrant hemianopsia, central or paracentral scotoma, or homonymous or heteronymous hemianopsia.
H. D. Lamb.

Kolačný, J. Disturbances of liver function and their relation to reduction of dark adaptation. Bratislavske Lekarske Listy, 1938, v. 18, Oct., p. 63.

Systematic adaptometric studies on patients with clinically recognized disturbances of liver function yielded in every case a reduction of ocular adaptation for darkness. Hemeralopia, however, was only manifested in a few cases, and was usually latent, the patient knowing nothing of its existence, and the hemeralopia being indicated merely by the adaptation curve. The author assumes that the hemeralopia existing in these cases is to be regarded as a consequence of disturbed rate of regeneration of the visual purple, caused by a deficiency in vitamin A. Such deficiency arises from disturbances of function in the liver, where the transformation of carotin into vitamin A takes place. Thus in cases in which disturbance of liver function is merely presupposed (but cannot be confirmed by existing clinical methods) the hemeralopia is to be regarded as an early symptom of this disturbance. After administration of vitamin A in the cases here reported, an improvement in adaptation was demonstrated adaptometrically.

1938, v. 12, pt. 4, p. 525. (See *Amer. Jour. Ophth.*, 1938, v. 21, Dec., p. 1407.)

Lancaster, W. B. *Aniseikonia*. *Arch. of Ophth.*, 1938, v. 20, Dec., pp. 907-912; also *Trans. Amer. Ophth. Soc.*, 1938, v. 36.

This term was coined by the author for a difference in size of the optical images of the two eyes. He discusses the consequences and symptoms arising from decompensation, and points out that the amplitude of adjustment in compensation for aniseikonia is limited as compared with the amplitude of accommodation or the amplitude of fusion. The chief causes of aniseikonia are anisometropia, the wearing of glasses of different magnifying power for the two eyes, and asymmetric convergence. When the eyes are unable to compensate for the aniseikonia suppression usually results. The three chief objections or criticisms to the claim that aniseikonia is an important factor in eyestrain are: first, that the benefit alleged to follow the use of eikonic lenses is really due to suggestion or psychotherapy, second, that eikonic lenses may have a considerable prismatic effect and may thus produce anisophoria, and third, that asymmetric convergence produces difference in size greater than many of the differences claimed clinically to cause symptoms but is compensated for by an automatic increase in the size of the optic image of the adducting eye.

J. Hewitt Judd.

Litinskii, G. A. *Monocular depth perception and the method of its determination*. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 532.

The author attributes the general belief in the absence of monocular depth perception to the fact that all depth-

perception apparatus is constructed for binocular tests. He describes an apparatus for measuring monocular tridimensional perception, which he designates as perception of solidity. He concludes that perception of solidity is a monocular as well as a binocular function. Its qualitative characteristics may be demonstrated on his apparatus. The physiologic threshold of solidity perception is 1 mm. for the better eye. In 72.5 per cent of cases monocular perception of solidity is equal to binocular perception, in the rest of the cases it is somewhat lower. The right eye is superior to the left eye in this function. Influence of sex and age is not apparent.

R. K. Daily.

Ludvigh, Elek. *Determination and significance of the scotopic retinal visibility curve*. *Arch. of Ophth.*, 1938, v. 20, Nov., pp. 713-725.

By utilizing experimental determinations of the selective absorption of light by the refractive media of the human eye, a scotopic ocular visibility curve, expressed in terms of energies, is transformed into a scotopic retinal visibility curve, expressed in terms of quanta by application of the Stark-Einstein law of photochemical equivalence. This curve is asymmetric and agrees with that representing the modern determination of the absorption spectrum of visual purple. The author briefly discusses the significance of the scotopic retinal visibility curve with respect to Kundt's rule, the Purkinje phenomenon, the purity of visual purple solutions, the b wave of the electroretinogram, and certain visual theories.

Maisler, S. *A new refractor suspension*. *Arch. of Ophth.*, 1938, v. 20, Oct., pp. 1044-1045. To an adjustable table

is attached a standard supporting a chin rest and a large loop of tubing from the top of which is suspended the refractor. The instrument is shown in a photograph. J. Hewitt Judd.

Mann, Ida. *Applied optics*. Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 109.

An excellent historical survey of the development of the contact lens in the one hundred years since Thomas Young presented the theory in *Philosophical Transactions* for 1801 is given. The subject is presented under three aspects, namely, the optical principles involved, the causes of intolerance, and the therapeutic indications.

Beulah Cushman.

Martin, L. C. *A standardized lantern for testing color vision*. Brit. Jour. Ophth., 1939, v. 23, Jan., pp. 1-19.

In an article not lending itself to abstract, the author discusses production and standardization of a lantern for use by the Board of Trade, with the Medical Research Council advocating employment of a similar lantern for the Royal Navy. The experiments which led to the standardization are fully discussed. (Figures, tables.) D. F. Harbridge.

Obrig, T. E. *A cobalt-blue filter for observation of the fit of contact lenses*. Arch. of Ophth., 1938, v. 20, Oct., pp. 657-658.

For observing the accuracy of the fit of a contact glass, a buffer solution containing one drop of fluorescein is used and is viewed with a dense cobalt-blue filter placed between the source of illumination and the eye. This produces a brilliant yellow-green glow wherever the contact glass is not in contact with the cornea or conjunctiva and a dark area where the lens touches the cornea and conjunctiva. J. Hewitt Judd.

Ogle, K. N. *Induced size effect: 1. A new phenomenon in binocular space perception associated with the relative sizes of the images of the two eyes*. Arch. of Ophth., 1938, v. 20, Oct., pp. 604-623.

The literature is briefly reviewed and the apparatus used for quantitative study of geometric and induced size effects is described. The data obtained are tabulated and are shown graphically. In addition to the change in apparent rotational position of the surface seen binocularly when a change is introduced in relative sizes of the ocular images in the horizontal meridian, a new and unexpected phenomenon of apparent rotation of the binocular visual field caused by a difference in the size of the image in the vertical meridian was found. Its exact cause is not clear. However, three facts have been determined. First, a one-to-one ratio of the maximum sensitivities of the induced to the geometric effect exists, though the two effects are opposite in sign; second, the effect reaches a maximum value for differences in size of the images in the vertical meridian greater than 5 or 6 percent; third, above this difference the induced effect decreases slowly. J. Hewitt Judd.

Ohm, J. *What is darkness? Remarks on the essay of Jac. v. Essen, etc*. Graefe's Arch., 1938, v. 139, pts. 4 and 5, pp. 811-816.

Ohm cannot agree with Essen's psychologic description of darkness as a lack of optical differentiation in space (see Amer. Jour. Ophth., 1939, v. 22, p. 206). To Ohm, darkness means objectively the absence of light, or of ether waves of certain wave-length, and blindness means not a blurring but an inability to perceive light. The study of

nystagmus teaches that in miners, and in young children who grow up in badly lighted dwellings, nystagmus results from insufficient lighting. Darkness is a positive experience to many blind persons, just as black and darkness are employed in common speech and poetry as something positive.

H. D. Lamb.

Seidel, E. The physiology of the process of accommodation in the human eye. *Graefe's Arch.*, 1938, v. 139, pt. 3, pp. 513-519.

Observations in a series of otherwise sound young albinotic human eyes were made with the eye focused for distant and for near vision while the direction of gaze remained unchanged. Examination with the ophthalmoscope disclosed that when the eye was accommodating to fix on a point at 10 cm. distance, the lens equator gradually contracted toward the lens axis, so that the equatorial diameter was diminished about 1 mm. If 1-percent atropine had been instilled one hour previously, this contraction of the lens equator did not occur.

Ray K. Daily.

Sudranski, H. F. An evaluation of homatropine-benzedrine cycloplegia. *Arch. of Opht.*, 1938, v. 20, Oct., pp. 585-596.

The refraction was determined for three groups of 25 patients, each group having similar age limits, to compare the cycloplegia obtained by homatropine hydrobromide plus cocaine hydro-

chloride, by homatropine and benzedrine, and by homatropine in one eye and homatropine-benzedrine in the other. Fifteen patients were studied to determine the exact cycloplegic effect of a 5-percent solution of homatropine and a 1-percent solution of benzedrine, used separately. The author concludes that a 5-percent solution of homatropine hydrobromide combined with a 1-percent solution of benzedrine sulphate may be recommended for production of cycloplegia, because the homatropine alone causes complete cycloplegia, the synergistic action between the two drugs produces good mydriasis, and the cycloplegia is of very short duration due to the small amount of homatropine used. J. Hewitt Judd.

Tron, E. Z. Refraction of the aphakic eye. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 445.

From study of aphakic eyes the original refraction of which was known, and from the calculated aphakic refraction of eyes which had been examined with Tscherning's ophthalmophakometer, the author concludes that the same original refraction may lead to various aphakic refractions, and that the same aphakic refraction may be found in originally different eyes. These variations are accounted for by different combinations of the anteroposterior axis of the eye, the refractive power of the cornea, and that of the lens. Variations in the refraction of the aphakic eye thus depend on the various optical combinations of the aphakic as well as the original eye. From the calculated coefficient of correlation between the refraction of the eye previous to and after extraction of the lens, it is evident that the refractive power of the lens is the most significant factor in variations in refraction.

Ziering, Josef. The function of the squinting eye and the squint deviation. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 759-789.

In examination of 112 patients with squint, the findings included the following information: (1) monocular function of the squinting eye, its ability to fix, visual acuity without and with correction, its visual field with the perimeter and scotometer; (2) whether and in what respect the squinting eye works with the fellow-eye; (3) the kind, amount, and character of the squint deviation. All the author's cases with high-grade amblyopia, where the visual fields could be determined, presented either a central (usually relative) or a paracentral scotoma. Amblyopia is caused by anisometropia, when no fusion exists, and the eye with less refractive error and the better image is used, the other eye ignored. When both eyes have about the same change of refraction, alternating squint prevails in the absence of fusion.

CONJUNCTIVA

Cornet, Emmanuel. Concerning some symptoms of trachoma described by Keller in 1937. *Rev. Internat. du Trachome*, 1938, v. 15, Oct., p. 165.

The author reviews several publications of Keller and discusses some of the points brought out. The disease is a familial one but primary infection may occur in the adult. The interstitial keratitis of syphilis is easily distinguished from the pannus of trachoma. Corneal sensitivity in trachomatous pa-

tients shows great variability, certain zones being more insensitive than others. The author distinguishes three varieties of trachoma: (1) pure trachoma, (2) paratrachoma or that secondarily infected, (3) that associated with other palpebro-conjunctivo-corneal diseases. J. Wesley McKinney.

De Lord. Treatment of trachomatous pannus by subconjunctival autohemotherapy. *Bull. Soc. d'Opht. de Paris*, 1937, July, p. 372.

Report of six cases treated with 1-c.c. subconjunctival injections of whole blood; at the same time using mercuric-chloride rubs on the superior tarsal conjunctiva. There was immediate improvement in the pannus.

Harmon Brunner.

Grüter, Wilhelm. Microstructure of epithelial cells and its significance for the etiology of trachoma. *Rev. Internat. du Trachome*, 1938, 15th yr., Jan., pp. 9-14. (In German.) (See *Amer. Jour. Ophth.*, 1938, v. 21, Aug., p. 946.)

Jaeger, Ernst. Operative method for pterygium. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 741.

The method is described in detail. Its advantages are: (1) Healthy conjunctiva lies opposite the disturbed corneal area, and this prevents a relapse. (2) The scar which closes the conjunctiva lies in healthy tissue above the diseased area, so that soft smooth cicatrization is possible. C. Zimmermann.

Kapuscinski, Witold, *Bacteriology of trachoma*. *Klinika Oczna*, 1938, v. 16, pt. 5, p. 664.

A lecture on trachoma for practicing physicians, covering thoroughly the published material on the subject.

Ray K. Daily.

Katznelson, A. B., and Pris, I. I. Phlyctenular eye diseases and tuberculosis. *Viestnik Ophth.*, 1938, v. 12, pt. 4, p. 447.

On the basis of 270 cases of phlyctenular keratoconjunctivitis the author comes to the following conclusions: a tuberculous etiology may be considered established on the basis of clinical and roentgenologic findings as well as of tuberculin reactions. The majority of cases of phlyctenular conjunctivitis occur between one and eleven years of age, and females are affected more frequently than males. The majority of patients have clinical and roentgenologic changes, active in character, in two thirds of the cases. In all cases, even in the absence of clinical signs there is a high sensitivity to tuberculin, although there is no parallelism between the intensity of the disease and of the tuberculin reaction. The younger the patient, the greater the percentage of clinical symptoms. Among the active forms of tuberculosis the infiltration type predominates. The presence of cavernous changes makes the prognosis of the ocular infection more grave. Active clinical tuberculosis is most frequently found in cases of avascular keratitis, less frequently in pannus, and in 50 percent of phlyctenular conjunctivitis. Phlyctenules of the limbus and avascular keratitis are early manifestations of tuberculosis. Pannus develops after recurrent attacks and is therefore seen in older people. Exacerbations of pannus keratitis are less dependent on the toxicity of the tuberculous focus than are other forms of phlyctenulosis. Phlyctenular keratoconjunctivitis is frequently the only symptom of active tuberculosis and should lead to early diagnosis of the disease.

Kirk, R., McKelvie, A. R., and Hussein, H. A. Sulphanilamide in the treatment of trachoma. *The Lancet*, 1938, v. 235, Oct. 29, p. 994.

Twenty-five cases of trachoma were treated by sulphanilamide by mouth, $7\frac{1}{2}$ grains three times a day for seven days, with seven-day intervals between courses. Encouraging results were reported, especially in cases showing pannus and keratitis. George A. Filmer.

Lijo Pavia, J. Prevention of blindness. Silver acetate or nitrate in the prevention of ophthalmia neonatorum. *Rev. Oto-Neuro. Oft.*, 1938, v. 13, July, p. 171.

The author feels that silver acetate is a safer drug to use than silver nitrate in Credé treatment of the new-born. The acetate is less soluble and therefore cannot be used in high concentrations. This obviates the possibility of corneal damage if too high concentrations are used by mistake. He believes the acetate is as effective as the nitrate.

Edward P. Burch.

Lijo Pavia, J., Irigoyen, L., and Tartari, R. A. Conjunctival xerosis. Anatomico-pathologic contribution. *Rev. Oto-Neuro. Oft.*, 1938, v. 13, Aug., p. 189.

The authors report two cases of xerosis of the conjunctiva which were observed clinically. A biopsy was made in one case and the tissue subjected to microscopic study. Essentially the lesion consisted of a regressive metaplasia of the conjunctival epithelium to the cutaneous type, with keratinization of the superficial layers, vacuolization and hyalinization of the malpighian layer, and invasion by melanophores and melanoblasts. The authors point out that the conjunctival lesions con-

stitute but one aspect of ophthalmic xerosis and that the visceral lesions which result from avitaminosis with respect to vitamin A may be of a very grave nature. (Photomicrographs.)

CORNEA AND SCLERA

Amsler, Marc. Minimal keratoconus of Javal. *Ophthalmologica* (formerly *Zeit. f. Augenh.*). 1938, v. 96, Nov., p. 77.

The author describes and illustrates a characteristic of minimal and incipient keratoconus by which it may be unequivocally recognized. It is an asymmetry of its surface reflections, readily demonstrated by means of the Placido disc or the mires of an ophthalmometer. The image of the horizontal axis of the Placido disc is not at right angles to that of the vertical axis, but deflected

several degrees. Such an angle also exists between the right and left images of the mires of the ophthalmometer.

F. Herbert Haessler.

Amsler, M. Note on the evolution of keratoconus. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 326-333.

Using as pathognomonic sign a depression of the horizontal axis of the keratoscopic image, obtained photographically, the writer reports his conclusions after study of 131 subjects, 105 of whom have been followed for over ten years. The malady makes its appearance in the years following puberty, has little tendency to progress, has never been observed to lessen or improve, is characterized often by crises of pain, redness, and severe irregular astigmatism. The crises disappear without seemingly being a part of any evolutionary changes in the malady.

Clarence W. Rainey.

Bonnet, P., and Gate. Interstitial keratitis observed in the secondary phase of acquired syphilis. *Bull. Soc., d'Opht. de Paris*, 1937, July, p. 417.

Interstitial keratitis developed in a 27-year-old female seven days after institution of arsenical therapy. About twenty Wassermanns had been negative in the two years before the positive reaction, after which treatment was given. There was the characteristic clouding of the corneal parenchyma, with deep vascularization.

Harmon Brunner.

Cornet, Emmanuel. Conjunctivoplasty of the cornea, quantitative vision. *Ann. d'Ocul.*, 1938, v. 175, Dec., pp. 914-916.

In cases unfavorable for keratoplasty, a central corneal leukoma may be ex-

cised and the defect covered by a sliding tongue of conjunctiva. As this flap heals over the hole, its translucency gives a completely blind eye "minimal vision."

John M. McLean.

Cornet, Emmanuel. A technique of corneal graft "in stenopeic slit." *Ann. d'Ocul.*, 1938, v. 175, Dec., pp. 910-914.

After a brief review of methods of keratoplasty, the author presents his method of grafting a horizontal rectangle. A conjunctival flap just wide enough to cover the graft and long enough to stretch across the cornea is prepared so that hinged at the limbus it will cover the graft, epithelial side down. The conjunctival defect is closed. The donor eye (apparently rabbit rather than human) is enucleated, washed in serum, and its entire cornea removed. This is placed in a special graduated clamp and a strip 3 mm. wide and 6 mm. long marked out on it. Intracorneal sutures are placed 1 mm. from each end and the graft excised. An area of the same size is marked on the recipient cornea, long axis horizontal, with a metal template, and is excised. Any presenting iris tissue is cut off. Cataractous lens, if present, is then extracted through this opening, extracapsularly. Any existing cyclitic membrane is incised. The intracorneal graft sutures are then passed through the edges of the defect in the cornea at the appropriate points and the graft drawn into place with them. The inverted conjunctival flap is fastened in place under tension and the corneal sutures tied over it. The corneal sutures are removed by the third day and the flap by the tenth.

No cases are described, nor are any results reported. John M. McLean.

Culler, A. M. The pathology of

scleral plaques. *Brit. Jour. Ophth.*, 1939, v. 23, Jan., pp. 44-50.

Described are five cases of degenerative plaques in the sclera mesially, one studied histologically. Each case is described in detail. The plaques occur chiefly in patients over sixty years of age. The opinion of the author is that no clinical symptoms arise from the lesions, and that the histological appearance is that of a degenerative rather than of a developmental defect. (Figures, bibliography.)

D. F. Harbridge.

Dejean and Artières. Experimental study of the healing action of insulin on corneal wounds. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 303-307.

Using three-month-old rabbits, the authors removed a superficial portion of the cornea with a 20-mm. trephine, and noted the time necessary for regeneration of the loss of substance, by observing the staining of the cornea with methylene blue. They conclude that a daily injection of 10 to 15 units of insulin shortens the healing period from two to four days. Insulin in ointment form did not have any effect.

Ellis, O. H. Superficial marginal keratitis. Clinical and anatomic findings in fellow eyes. *Amer. Jour. Ophth.*, 1939, v. 22, Feb., pp. 161-168.

Kapuscinski, W. The influence of radium on interstitial keratitis. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 308-317.

The optimum dose was found to be 66 mg. of radium element, placed in a platinum filter 1 mm. thick, held at a distance of 2 cm. from the eye for six hours. The majority of the patients had the disease six months or less. The final

vision of twenty-two percent was 5/5. The best results were obtained in the earliest cases. Improvement was noted in a few weeks, and took place more rapidly and to a greater extent than in untreated cases. The author did not observe the formation of cataract in any of the cases treated.

Clarence W. Rainey.

Motolese, A. Hypopyon keratitis and hypertony. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 382-399.

The author studied the effect of induced hypertension upon the course of infected ulcers of the rabbit cornea produced by inoculating the cornea with streptococci, pneumococci, and staphylococci. He concludes that hypertension exerts an unfavorable influence upon the course of the disease.

Clarence W. Rainey.

Pandelese, C., and Valdman, J. Rosacea keratitis. *Arch. d'Opht.*, etc., 1938, v. 2, Dec., p. 1080.

The authors review the literature and history of rosacea keratitis, and describe three typical cases. They point out the polymorphism of the lesion, varying from true ulcers to simple zones of infiltration and leucomata of fibrous tissue. The blood vessels vary in size according to the stage of the lesion, being largest in the ulcerous stage. The limiting furrow of the necrotic lesion is deeper in one part than another. The cicatricial opacities lie over an area of cornea which is thinned. The authors treated the cases with success, using 1-percent silver nitrate, zinc-ichthyol ointment, milk diet followed by a milk and vegetable diet, and occasional dry heat from the galvanocautery. (Bibliography.)

Derrick Vail.

Rhodes, A. J., *Studies on the bacteriology of hypopyon ulcer*. Brit. Jour. Ophth., 1939, v. 23, Jan., pp. 25-42.

This paper is the first in a series of studies carried out by the W. H. Ross Foundation for the Study of Prevention of Blindness.

Under part 1, concerning the conjunctival flora of healthy coal-mine workers, the author deals with preparation of cultures, classes of workers examined, mines visited, controls, and results. It was found impossible, because of varying conditions of dust, moisture, ventilation, and so on in the various pits, to compare one mine worker with another. The percentage of various organisms in the whole pit is noted in some instances, while the percentage present in the total of 658 men examined is recorded in others. *Staphylococcus albus* and diphtheroid bacilli were present in quantity, while pigmented staphylococci were not so commonly found. Underground workers did not demonstrate a flora essentially different from that of surface workers. Those most apt to contract the disease are those most exposed to corneal trauma, or the miners and brushers. Under part 2, as to the conjunctival flora of shale-mine workers, the same procedures are reviewed, with the finding that shale-mine workers nurture a flora composed in part at least of potential pathogens. The opinion is maintained, as based on both types of mine workers examined, that the source of infection in hypopyon ulcer is from organisms already present in the conjunctival sac and that the conjunctival flora definitely exposes the mine worker to infection. (Tables, references.) D. F. Harbridge.

Rubbrecht, R. *The surgical treatment of corneal conditions*. Bull. Soc.

Franç. d'Ophth., 1938, v. 51, pp. 318-325.

The author discusses a method of transplanting a thin layer of neighboring conjunctiva, which is generally applicable to a large number of corneal maladies, especially those of the epithelium and the superficial layers. The affected tissue is excised with a special lancet, and the loss of tissue covered with bulbar conjunctiva. The corneal transparency is greater than from the scar of the original process.

Clarence W. Rainey.

Terry, T. L. *Some physiological and anatomical aspects of the cornea affecting its pathology*. Amer. Jour. Ophth., 1939, v. 22, Feb., pp. 153-155.

Thomas, J. W. T. *Corneal transplantation*. Brit. Med. Jour., 1938, Oct. 8, p. 740.

Results of 56 operations on 48 eyes are given. The technique was the same as used by the author in his previous cases, except for two modifications; namely, using saline instead of oil for receiving the graft, and so arranging the cross stitches that the knots do not lie on the graft or its edges.

Over 60 percent of the operations and 66 percent of the eyes operated on were successes. Five of the nine cases of old interstitial keratitis exhibited clinically transparent grafts. Out of thirty cases observed for a period of years, six showed deterioration and one actually improved. With the modified technique now used, it is anticipated that the deterioration of 20 percent of the grafts over a period of years will be considerably reduced. F. M. Crage.

Wille, W. A. *Keratitis ramificata superficialis and its connection with*

asthenopia, blepharospasmus nictitans, and pterygium. *Brit. Jour. Opth.*, 1938, v. 22, Dec., pp. 705-722.

The author believes that this disease has not been discussed in ophthalmic literature although he himself described it in 1914 in a medical periodical in the Dutch East Indies. The disease confines itself to the epithelium. A thin layer of lacrimal fluid which always covers the cornea must be evaporated before the condition is manifest. The specific relationship between this eye disease and pterygium is pointed out and described. The disease is rather common in the tropics, the author having treated many cases in Java, a number of which are described. He regards the disease as due to climatic conditions such as heat, glare, wind, and dust. Some living agent seems to be indicated by the racemose way in which the disease advances. (Case histories, figures, tables.)

D. F. Harbridge.

Zobel, Hans. Sensitivity of the cornea in different periods of life. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 668-676.

For this study, the normal corneae of 261 females and 270 males, together with 54 pathologic cases, were examined as to sensitivity. In the normal cornea, this was found to gradually increase in degree with age, until it attained a maximum between 45 and 50 years. Thereafter, it diminished more rapidly with age to reach a minimum between 80 and 90 years. These changes of sensitiveness are more definite peripherally than centrally in the cornea. The author was able to confirm the fact that the sensibility of the cornea diminished from its center toward the limbus.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Alexseev, V. I. Pigment allergy in sympathetic ophthalmia. The significance of the intradermal test. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 468.

A review of the literature and a tabulated report of intradermal tests of 26 patients with uveitis pigment, prepared by the author. In six cases the cutaneous reaction areas were excised and examined histologically. The intradermal tests were positive in five cases of sympathetic ophthalmia, in two with traumatic iridocyclitis, and in one of recurrent iritis. The reaction was negative in one case of sympathetic ophthalmia and in seventeen cases of traumatism. Pathologically, the excised cutaneous segments had extensive proliferation of cells belonging to the reticulo-endothelial tissues. Of the six cases examined, in five the gross findings agreed with the microscopic. In one case the skin test was clinically negative but microscopically positive.

Ray K. Daily.

Lagrange, H., and Goulesque, J. Iritis and focal infection. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, p. 334.

This article is practically an abbreviated paraphrase of a previous article on the same subject (see *Amer. Jour. Opth.*, 1938, v. 21, p. 1292).

Okolow-Hryniewiczowa, Z. Sympathetic ophthalmia. A report of three cases of sympathetic ophthalmia with favorable result. *Klinika Oczna*, 1938, v. 16, pt. 5, p. 539.

The local treatment consisted of homatropine, atropine, dionin, and hot fomentations. General treatment consisted in the intravenous administra-

tion of arthrosan (sodium phenylcinchonate and sodium salicylate) auto-hemotherapy, intravenous injections of urotropin, and increasing doses of an antituberculous antigen. The author stresses the fact that sympathetic ophthalmia is not an incurable disease but that treatment must be instituted before irreparable damage has been done. For early diagnosis examination with the slitlamp is indispensable.

GLAUCOMA AND OCULAR TENSION

Csillag, Franz. Essential atrophy of the iris and glaucoma. *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 874.

Two cases are reported, in which the atrophy arose from the tension and from disturbance of the blood supply of the iris. The glaucoma complicating the iris atrophy was secondary. The tension was lowered by pilocarpine, and even reached normal.

C. Zimmermann.

Greenwood, Allen. Surgery of secondary glaucoma. *Amer. Jour. Surg.*, 1938, v. 42, Oct., pp. 10-13.

In sarcoma of the choroid and in cases of complete obstruction of the central vein of the retina followed by hypertension, enucleation is the only adequate surgical measure. Tuberculin in minimal doses instead of surgery is recommended in tuberculous uveitis. After cataract extraction and contusion and in cases of iritis, medication will

usually hold the tension, but a simple iridectomy may be needed.

Ralph W. Danielson.

Kaminskaja, Z. A., and Gubina, H. M. The diagnostic significance of the Seidel test. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 479.

The authors' observations demonstrate that Seidel's reaction is reliable only in cases of glaucoma with an active iris sphincter. In absolute glaucoma with iridoplegia the reaction was negative. No relation could be demonstrated between this reaction and dispersion of the iris pigment. The author believes that the increased tension is due to liberation of chemical substances into the aqueous by dilatation of the pupil.

Kayser, B. May central scotoma with intact peripheral borders or concentric narrowing of the visual field be compatible with a diagnosis of glaucoma? *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 883.

The author has reported (see *Amer. Jour. Ophth.*, 1934, v. 17, p. 273) an extreme case of this kind in a woman in whom observation from her fiftieth to her seventy-fifth year had negated a diagnosis of glaucoma. He examined the patient again in her eightieth year. The right disc showed the same excavation of 6 or 7 D., the left from 3 to 4 D. (of glaucomatous character). Vision was 1. The tension was 28 mm. In spite of the development by 1926 of a central scotoma and marked concentric contraction of the visual field as well as the later developments as to tension and excavation of discs, the diagnosis of glaucoma is still rejected.

Noble, R. L., and Robertson, J. D. The effect of hypertonic solutions on

gastric secretion and intraocular pressure. *Jour. of Physiology*, 1938, v. 93, Sept. 16, p. 430.

In animals where gastric secretion and intraocular pressure have been measured, it has been found that following intravenous injections of 30-percent NaCl 5 c.c. per kg. at the rate of 2 c.c. per minute there was a striking fall in the pressure of the eye and in volume and acidity of gastric juice. Fifty percent glucose had to be given in more than three times the amount and rapidity of the 30-percent NaCl to obtain similar results.

These solutions caused a dilution in hemoglobin which rapidly returned to normal. Intraocular pressure was markedly lowered and remained so for some hours. This was quite independent of the variations in blood pressure. The findings indicate that dialysis is not a satisfactory explanation of the formation of the aqueous humor. A similarity in response to hypertonic solution between gastric secretion and intraocular pressure suggests that a secretory process may play some part in controlling intraocular pressure. F. M. Crage.

Tatár, Josef. Glaucoma in Cushing's disease. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 793-800.

In a 24-year-old farmer's wife with Cushing's disease, there occurred a periodic increase of tension of both eyes with pronounced constriction of the visual fields. This increase of tension was considered to be due to a senilitas praecox as well as to hyperfunction of the adrenal cortex. The considerable contraction of the fields was partly the result of the increased tension but was possibly associated with spastic changes in the retinal arteries.

CRYSTALLINE LENS

Bakker, A. The importance of the iris in the production of infrared cataract. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 667-703.

Rabbit lenses, transplanted to a constant-current tissue-culture, were exposed to rays of an electric incandescent bulb and to those of an arc light. In the genesis of heat cataract, not only the penetrating infrared but also the long-wave infrared rays are important. In both series of experiments the iris played a definitely important part in the production of cataract. A notable specific absorption of the penetrating infrared rays could not be demonstrated for the lens. Infrared rays, after having passed through the entire thickness of a lens without causing the least injury, caused extensive opacities in a second lens covered by its iris. Cataract in the posterior cortex was produced purely by the action of the iris, when all direct rays were excluded. The typical posterior cortical cataract of glass-blowers cannot be the result of direct action of the rays. The so-called specific ultrared cataract of Vogt's experiments is nothing but an ordinary heat cataract.

H. D. Lamb.

Bangerter, A. An unusual case of diabetic cataract. *Ophthalmologica* (formerly *Zeit. f. Augenh.*) 1938, v. 96, Nov., p. 98.

In a child of eleven years, the entire lens of each eye was occupied by fine punctate opacities such as are usually found in the cortex. The planes of optical discontinuity were not visible. This observation does not support the generally held belief that exogenic noxa can only produce superficial lenticular

changes before disintegration of the lens takes place.

Berens, C., and Bogart, D. W. Certain postoperative complications of cataract operations. *Amer. Jour. Surg.*, 1938, v. 42, Oct., pp. 39-61.

Analysis of the results of 1,004 operations and review of the literature. Thirty percent were intracapsular. Preoperative examination and precautions are stressed. (12 figures, 13 tables, 104 references.) Ralph W. Danielson.

Corboy, P. M. A corneoscleral union for cataract operations. *Amer. Jour. Ophth.*, 1939, v. 22, Feb., pp. 174-175.

Podesta, H. H., and Bancke, J. The source of vitamin C in the different tissues of the eye. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 720-731.

Investigation showed that in cattle, horses, and sheep the concentration of vitamin C was increased from the ciliary body and iris through the aqueous humor to the lens. These conditions for vitamin C were found reversed in rabbits, dogs, and guinea pigs. As regards the synthesis of vitamin C, rabbit lenses showed no demonstrable ability, cattle lenses had a strong action, and in guinea-pig lenses it varied according to the extent of the fall of vitamin C from lens to ciliary body and iris, from none to a moderately strong synthetic capacity. H. D. Lamb.

Reiser, K. A. Our experiences with intracapsular cataract extraction. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 692.

At the Bonn eye clinic intracapsular extraction has been used since 1932. The advantages and disadvantages of this method are discussed on the basis

of 300 cases and the results compared with 100 extracapsular extractions. Intracapsular extraction is technically somewhat more difficult. Prolapse of vitreous is more frequent, as well as postoperative iris prolapse. The advantages are: Intracapsular extraction is a single procedure. The physiologic relations (round movable pupil, no adhesions of the pupillary margin) are better preserved. Speedy healing is had without irritation. The visual results are better. In all cases of cataract, except congenital, the intracapsular method was attempted, and it succeeded in 72.2 percent. It should be tried in every case from the minimum age of 40 years, in incipient senile, nuclear, posterior cortical, complicated, and contusion cataract. A contraindication exists in all congenital and acquired cataracts up to the fortieth year of age. C. Zimmermann.

Riad, M. Congenital familial cataract with cholesterin deposits. *Brit. Jour. Ophth.*, 1938, v. 22, Dec., pp. 745-749.

After citations from the literature relative to this hereditary condition, cases are reported. Discussion is based on the history of two half sisters. In the thirteen cases examined, there was no history of consanguinity, nor of mental disturbance or convulsions. Hereditary influence was strongly marked in the females, with continuous descent followed through three generations from an affected female. No constitutional diseases were noted. The author bases his opinion that such cataracts are of congenital origin on the premise that the opacities are seen in the central embryonic nucleus. This is further substantiated by the similarity of all cases and the presence of the condition in both eyes. The type of cataract is fully described. The per-

centage of cholesterol in the blood was diminished according to the findings here presented. (Figures, references.)

D. F. Harbridge.

Salit, P. W. The mineral content of cataractous and sclerosed human lenses. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 654-667.

Altogether 115 cataractous and sclerosed human lenses were analyzed as to the content of potassium, sodium, calcium, chlorine, phosphorus, and sulphur in their ash. The average weight of ash in incipient cataract amounts to 0.921 percent, that in mature cataract 1.067 percent of the moist weight. When one compares this amount with the dry weight and water content, it is found to represent 2.836 percent and 1.392 percent for incipient and 4.010 percent and 1.427 percent for mature cataract respectively. The average content of ash in mature cataract therefore exceeds that of incipient cataract by 16.0 percent, 41.0 percent and 2.5 percent on the basis of the moist weight, the dry weight, and the water content, respectively. The much greater difference in percentage estimated in comparison with the dry weight arises from the small amount of solid substance in mature cataract as compared with that of incipient cataract.

When one compares the total sum of electrolytes by percentage of the dry weight, this increases with advancing stages of cataract and of sclerosis, as a result of the diminution of solid substances in cataractous as well as in sclerosed lenses.

H. D. Lamb.

Urbanek, J. The C-vitamin metabolism of cataract patients. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 670.

In a former article (see *Amer. Jour. Ophth.*, 1938, v. 21, p. 1416), the author showed that in most cases of postoperative hemorrhages in cataract patients a lack of vitamin C could be held responsible. By saturation experiments with vitamin C and by regular administration of vitamin C in cataract patients, postoperative hemorrhage into the anterior chamber was entirely prevented. The author now reports on further tests. Saturation was judged from the quantity of excretion in the urine. The observations are given in tabular form with the following results: (1) The juvenile organism is better provided than the senile with vitamin C. (2) Development of cataract in old people does not always run parallel with a notable C-avitaminosis. There are well nourished cataract patients whose vitamin C condition equals that of the youthful organism. (3) From the fact that the senile organism is poorer in vitamin C one must not conclude that development of cataract is a consequence of C-avitaminosis. (4) The constancy of ascorbic acid in the aqueous, independent of the saturation of the organism, indicates that increase and decrease of vitamin C probably occur more slowly than in the blood serum. (5) The lens is not necessary or responsible for the formation or accumulation of vitamin C in the aqueous. The author's attempts to arrest or clear up incipient opacities of the lens of the second eye in cataract patients showed no satisfactory results.

C. Zimmermann.

Vogt, Alfred. First histologic finding of lens-capsule precipitates. *Klin. M. f. Augenh.*, 1938, v. 100, Nov., p. 703.

Three precipitates on the posterior surface of each cornea in a woman of 76 years, who had had lens-capsule glaucoma in the right eye (enucleated in 1932) are described and illustrated.

C. Zimmermann.

Vogt, Alfred. Further as to clinical course and histology of senile desquamation of the anterior capsule. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 705.

The lamellae projecting into the anterior chamber were observed with the slitlamp for years, and now after death of the patients have been examined anatomically. They show how oval vacuoles in the superficial layers of the capsule pave the way for destruction. The eyeballs were enucleated immediately after death.

C. Zimmermann.

10

RETINA AND VITREOUS

Damel, C. S. Preretinal hemorrhage. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, June, p. 283.

This is a lengthy discourse upon the pathogenesis, evolution, and ophthalmoscopic appearance of preretinal hemorrhages. The historical aspect of the subject is reviewed. The author feels that preretinal hemorrhages may be explained on the basis of venous stasis, this being the case whether the basic cause of the hemorrhage is sclerosis of the retinal vessels, head injury, or periphlebitis. The article is profusely illustrated with fundus photographs and diagrams. Edward P. Burch.

Dubois-Poulsen. The action of hypophyseal extract and adrenalin on the fringes of the pigment epithelium of the frog. *Bull. Soc. d'Ophth. de Paris*, 1937, July, p. 377-380.

The action was found to be the same as that on the skin. Controls were run in sunlight and darkness. Hypophyseal extract caused retraction of the fringes of retinal pigment. Adrenalin caused extension. The author confirms the epidermal origin of the pigment. A similar action may occur in man, in whom adrenalin is known to accelerate dark adaptation. Harmon Brunner.

Grafova, Kornelia. Detachment of the vitreous. *Klinika Oczna*, 1938, v. 16, pt. 5, p. 576.

A tabulated report of the examination of 37 eyes, in 28 of which vitreous detachment was found. The author reviews the literature and concludes from her findings that vitreous detachment does not predispose to retinal detachment but on the contrary prevents it; and that detachment of the vitreous and of the retina are caused by the same pathologic process within the eye. (Illustrations.) Ray K. Daily.

Hofe, K. vom. Changes in the fundus from diabetes. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 801-810.

The most characteristic finding in the fundus from diabetes is the dots of hemorrhage lying superficially and in the deeper layers of the retina. The white foci in the retina are white only when located superficially in the retina. When they lie in the deeper retinal layers, they are more dull and light gray, tinged with yellow or at times greenish. The white foci occur also in arterial hypertension and other diseases. In the majority of patients with diabetic retinal changes an increase of blood pressure exists. Usually, when retinal changes are present, the amount of blood sugar varies between 0.15 and 0.35. Acetone and aceto-acetic acid are frequently absent. An increase of fats

in the blood is generally found in the presence of retinal changes from diabetes. Nevertheless, the lipoid content of the blood is frequently increased when no retinal changes occur. In the majority of cases with diabetic changes in the fundus, the patients are not young and the diabetes has been present more than five years. From the metabolic disturbances in diabetes, there occur injuries to the vessels. The latter lead to nutritional disturbances of the retinal tissue. The white foci represent the reaction of the retina to its disturbed nutrition.

H. D. Lamb.

Kinukawa, C. Two cases of eclamptic retinitis (gravidarum) with pathologico-anatomic findings. Graefe's Arch., 1938, v. 139, pts. 4 and 5, pp. 640-653.

As in albuminuric retinitis, so also in eclamptic retinitis, the inner retinal layers are always normal and entirely free of edematous loosening of the tissue. The changes in the choroidal vascular system, and of the retinal pigmented epithelium, cause the diffuse opacity in the fundus in eclamptic retinitis. The clinical appearance of a so-called glassy retinal edema in eclamptic retinitis is most probably dependent upon a focal collection of subretinal fluid accompanied by no damage to the overlying retina. A change of the retinal pigmented epithelium in eclamptic retinitis, not previously noted, is pronounced pyknosis and atrophy of the nucleus. This indicates here, as in the liver and kidney, rather the injurious action of toxic material than a simple disturbance of nutrition.

H. D. Lamb.

Klemens, F. The presence of cystoid degeneration in the periphery of the retina and its relation to the new-

formed vascular layer. Graefe's Arch., 1938, v. 139, pts. 4 and 5, pp. 743-758.

The formation of hollow spaces in the periphery of the retina occurs at every age. This cystoid degeneration originates and develops independently of the new-formed vascular layer between the pigmented epithelium of the retina and the lamina vitrea, described by Löhlein. The cause of the formation of hollow spaces in the retinal periphery is still not satisfactorily explained.

H. D. Lamb.

Koyanagi, Y. What does integrity of the retinal periphery in albuminuric retinitis indicate? Klin. M. f. Augenh., 1938, v. 101, Dec., p. 844.

The author opposes the theory of Volhard that albuminuric retinitis is due to angiospastic disturbance of nutrition. According to him, integrity of the periphery indicates chiefly a detrimental effect of toxic substances, as there are no known cases of nutritional disturbance of the retina with intact periphery.

C. Zimmermann.

Pischel, D. K. Late results in retinal detachment operations. Amer. Jour. Ophth., 1939, v. 22, Feb., pp. 130-134.

Rumbaur, W. Rare causes of detachment of the retina. (a) lues, (b) flaming nevus. Klin. M. f. Augenh., 1938, v. 101, Dec., p. 866.

The right eye of a woman of 44 years, who denied venereal infection, showed diffuse chemosis caused by episcleritis. At the lower half of the fundus was a large vesicular detachment of the retina covering the disc and the macula. Repeated punctures of this by sclerotomy evacuated subretinal yellow fluid. The Wassermann reaction was positive. Antisyphilitic therapy restored vision to 3/60 with reattachment of the retina.

which was apparently due to transudation of serum from some syphilitic choroidal vessels. A connection with the episcleritis could not be determined with certainty.

An otherwise healthy, robust, non-myopic man of 23 years, upon stooping after strenuous bodily exertion, developed detachment of the left retina, and the eye became blind. After twelve years a detachment of the right retina occurred after similar physical exertion. The patient had an extensive flaming nevus of the whole face, with elephantiasic, proboscis-like thickening of the upper lid and angiomatous vascular changes in the outer tunics of the eye, but not involving the interior. Very probably the cause of the retinal detachment was associated with the nevus flammeus as well as the unusual bodily exertion. C. Zimmermann.

Sakler, B. R. **Retinal detachment.** Amer. Jour. Ophth., 1939, v. 22, Feb., pp. 175-179.

Sobhy Bey, M. **My experiences in retinal disinsertions.** Acta Ophth. Orientalia, 1938, v. 1, Oct., p. 1.

The author reviews the different methods employed for treating disinsertion of the retina at the ora serrata. He is in favor of diathermy but uses catholysis for larger disinsertions. He obtained a perfect cure in four instances out of the eight cases he reports. Disinsertions starting in the nasal and inferior parts have the best prognosis, those in myopic eyes give the worst results. R. Grunfeld.

Sorsby, Arnold. **Vital staining of the retina.** Brit. Jour. Ophth., 1939, v. 23, Jan., pp. 20-24.

First comes a summary of procedures and investigations in this subject dat-

ing back to the sixteenth century. Under the headings of "experimental observations" and "clinical applications" the author presents his findings and technique. The purpose of the article is to demonstrate that the procedure is practicable rather than to show the scope of staining. The fundus appearance in a case of retinal detachment, after intravenous injection of 20 c.c of Kiton fast green V, 10 percent, is shown by a photomicrograph. (References.) D. F. Harbridge.

Tsopelas, B. **Treatment of three cases of occlusion of the central retinal artery with eupaverin Merck.** Klin. M. f. Augenh., 1938, v. 101, Dec., p. 830.

In two out of three cases of nonembolic occlusion of the central retinal artery, the spasmolytic action of intravenous injections of eupaverin seemed to have favored recovery of some vision and visual field. The author is encouraged to continue his attempts with eupaverin in the different types of occlusion of the retinal arteries. He lays the greatest importance on very early use of the drug. C. Zimmermann.

Vogt, Alfred. **Subvascular white precipitates in the detached retina.** Klin. M. f. Augenh., 1938, v. 101, Dec., p. 864.

These white plaques involving large parts of the detached retina are most numerous in the intermediate zone and may cover the vessels. After operative healing of the detachment they disappeared in all of the author's cases. Their histologic basis is still unknown. C. Zimmermann.

Vogt, Alfred. **Symmetric relations of groups of retinal holes to terminal vessels.** Klin. M. f. Augenh., 1938, v. 101, Dec., p. 861.

Vogt has shown that almost all branches of a retinal terminal vessel, may be in relation with holes and grapelike cysts. He now records an emmetropic patient of 50 years in whom these appearances were symmetric in both eyes. The temporal periphery of the left retina presented ten holes, the nasal none. There were some in the temporal region of the right retina. Prophylactically Vogt closed the holes by catholysis and diathermy puncture. Other cases have shown symmetric obliteration of terminal vessels, leading to cystoid degeneration and formation of holes with or without detachment. Many of the author's previously recorded cases of inheritance of retinal detachment illustrated this anatomic predisposition, and the present instance proves such predisposition by symmetric occurrence in the individual.

C. Zimmermann.

Wasserman, I. New ideas on the treatment of retinitis pigmentosa. *Arch. d'Ophth.*, etc., 1938, v. 2, Dec., p. 1088.

In 1935 Lauber described his treatment of tabetic optic atrophy by lowering the intraocular tension and simultaneously elevating the blood pressure. In 1936 he applied the same treatment with apparent improvement in thirteen cases of retinitis pigmentosa. He has repeated this work in eleven cases of retinitis pigmentosa. In most of them he found the intraocular tension to be above normal. Six of his cases were definitely improved in from two to seven months by miotics and measures to elevate the blood pressure (caffeine, strychnine). Improvement of vision was noted in almost all of the cases. Enlargement of the visual field was found in only three cases. Lowering of intraocular tension is easier to obtain

than elevation of blood pressure. (*Bibliography.*)
Derrick Vail.

Wilczek, M. Anomalous vascular supply of the retina. *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 841.

The right eye of a man of 43 years, which had been blind for a long time, showed with +8.00 sph. an oval violet disc and very narrow arteries emanating from it. Around it was an irregular yellowish-white avascular area, and around this area were numerous gray foci with pigment. Five large and two small arteries emerged here, supplying a large part of the retina. A greyish strand running into the vitreous represented perhaps a remnant of an atypical accessory hyaloid artery. The lens had been absorbed, leaving a small grayish-white granule adherent to the pupillary margin. The white area seemed to be some sort of aplasia of the choroid, and the whole aspect spoke for a malformation due to disturbed development of the retinal pigment epithelium.

C. Zimmermann.

Wright, W. D. Light adaptation at the fovea for normal eyes. *Brit. Jour. Ophth.*, 1939, v. 23, Jan., pp. 51-66.

Findings of more than one hundred observers are recorded and analyzed, a new model of the subjective photometer being described. The sensitivity of the right eye in relation to the left when both eyes are dark-adapted, the adaptation factor, and the recovery curve are included in the data presented, as well as results as to reaction to glare, as to the photochemical reaction in the retina, and as to adaptation of the method for pathologic investigations. (Figures, references.)

OPTIC NERVE AND TOXIC
AMBLYOPIAS

Carillo, R., Malbran, J., and Chichilnisky, S. Barbituric retrobulbar neuritis. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, July, p. 370.

In 1937 Zwillinger and Trotot reported a case of retrobulbar neuritis due to veronal intoxication. This case is summarized by the authors, who in addition report the cases of two sisters who suffered from retrobulbar neuritis after ingestion of luminal taken with suicidal intent. The elder sister, who was addicted to the use of luminal suffered a profound systemic reaction, while the younger sister was less affected, although both took the same amount of drug on this occasion.

In each case there were visual disturbances. The elder sister exhibited nerve-head changes and depression of the peripheral field of vision, especially in the vertical isopters of the left eye. There was also a central scotoma with enlargement of the blind spot in this eye. In the right eye the peripheral field exhibited changes similar to those found in the left eye but in lesser degree. The younger sister showed only an enlarged blind spot in one eye.

The authors conclude that if the pressure within the central retinal artery is low, as determined by the method of Bailliart, the prognosis is unfavorable. Intravenous strychnine therapy is indicated for this type of intoxication, and vasodilator drugs may prove a useful adjuvant. Edward P. Burch.

Dimitriou, T. E. The relation of tabetic optic atrophy to changes of general blood pressure and intraocular tension. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 704-719.

The specific degenerative character of tabetic optic atrophy is contrary to any explanation of its changes by purely circulatory damage. The latter is not supported either by the fact that an exceptionally benign course of the atrophy occurs in those cases combined with glaucoma simplex. Hypotony of blood pressure is also absent in many of the cases here cited in the writer's own statistics. For normal nutrition of tissue, it is not the height of the diastolic but the average arterial pressure that is significant. In cases of luetic aortic insufficiency, the diastolic pressure may be very low and the intraocular tension relatively high without papillary atrophy occurring.

H. D. Lamb.

Grolman, Gunther von. Familial pseudo-optic neuritis. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, July, p. 368.

Pseudo-optic neuritis occurred in father and son. Edward P. Burch.

Hartman, E., David, M., and Guillaumat, L. Neurosurgery in certain syphilitic situations with involvement of the optic nerves. *Ann. d'Ocul.*, 1938, v. 175, Dec., pp. 877-893.

Four cases of syphilis of the central nervous system underwent craniotomy for brain tumor with resultant improvement of the involved optic nerves. Two patients with papilledema, one from frontal-lobe gumma, one from gummatous cyst of the fourth ventricle, were relieved of the papilledema with retention of normal vision. The vision in one case of edema of the brain in secondary syphilis was improved from $\frac{1}{3}$ to $\frac{3}{4}$ in each eye by decompression. A tabetic showed improvement in visual fields and acuity after operative re-

removal of adhesions from opticochias-matic arachnoiditis.

VISUAL TRACTS AND CENTERS

Cremer, Max. Early amaurosis from diffuse cerebral sclerosis. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 750.

A boy of three years had shown signs of amaurosis for about three months. As the fundi and the pupillary reactions to light were perfectly normal, a process at the calcarine fissure was assumed. Neurologic examination gave negative results. Gradually convulsions and contractions of the limbs and tongue set in, so that the child could take only liquid food. At the age of five years he died. The autopsy revealed a chronic sclerosing process, destruction of all myelin sheaths, fine nuclear fatty degeneration, and perivascular cell infiltrations.

C. Zimmermann.

Custodis, E. Meningioma of the falx; Foster-Kennedy syndrome misleading with regard to localization. *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 823.

A man of 41 years complained of frequent headaches since 1933. The right eye showed choked disc with normal vision and visual field. The left eye had vision of 6/60 with absolute scotoma for all colors and relative scotoma for white. The temporal half of the optic disc was pale. Tonic spasm of the facial nerve and paresis of the right abducens developed later. At operation a multicellular meningioma of the falx was removed. It had crowded aside the right frontal lobe of the brain.

Feigenbaum, Aryeh. Certain responsive bitemporal disturbances of the field of vision (excluding those caused by true tumors of the pituitary body) in some endocrine-vegetative affections. *Acta Ophth. Orientalia*, 1938, v. 1, Oct., p. 28.

Case histories of six female patients are given. They showed a bitemporal disturbance of the field of vision with signs of insufficiency of the pituitary gland but with normal sella turcica. After dehydration therapy the field defects returned to normal. From this the author concluded that the defects were the outcome of swelling of the tissues around the diencephalon, the pituitary body, and the chiasm. The transitory hemianopsic disturbances during pregnancy can be explained upon a similar pathology.

R. Grunfeld.

Friemann, Werner. Rotatory pendulum oscillations, identical with miner's nystagmus, in a tumor of the hypophyseal region. *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 848.

A man of forty years complained for three weeks of headache, vertigo, and impairment of sight. Both discs were pale and there was temporal hemianopsia. The roentgenogram showed a widened sella turcica with atrophic dorsum. Roentgen radiation had a good effect on vision. After six months the patient complained of subjective movements and nystagmus when looking upward, but vision had improved to 5/7. The nystagmus disappeared after scopolamine. The observations in this case suggested that damage of the cerebral stem might elicit characteristic pendulum oscillations resembling miner's nystagmus. An inquiry after a year revealed that the oscillations had ceased for several months.

C. Zimmermann.

Löhlein, Walter. **Permanent damage of the visual path in aviation.** *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 818.

At an altitude of from 5,000 to 6,000 meters, an aviator suddenly suffered from headache, vertigo, and obscuration of the visual fields. After landing he showed vertigo, nystagmus, and right-sided hemianesthesia and hemianopsia, due to a total scotoma from the macula to 40° in each eye. This persisted at examination after three months. Vision was 4/4. The disturbance was attributed to rupture of a cerebral blood vessel in the visual path above the optic tract, due to circulatory change at high altitude.

C. Zimmermann.

Ohm, J. **Remarks on the article by Friemann (see above).** *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 852.

Ohm assumes that in Friemann's case the nystagmus was not caused by the hypophyseal tumor itself or by changes in its immediate neighborhood, but by remote action of a disturbance in the vestibular nuclear apparatus.

C. Zimmermann.

Velhagen, K., Jr. **Indirect heteronymous hemianopsias.** *Klin. M. Augenh.*, 1938, v. 100, Dec., p. 801.

The author shows, on a series of cases, that bitemporal and binasal defects of the visual fields occur as indirect and remote symptoms of processes increasing intracranial pressure which are not located near the chiasm. The question is discussed how far these disturbances of the visual fields may be caused by damage to the sella from increased intracranial pressure. Here hydrocephalus of the third ventricle probably plays the chief part. The possibilities of differential diagnosis be-

tween indirect and direct heteronymous hemianopsias and direct and indirect destruction of the sella are considered.

Klikova, O. L., and Tokareva, B. A. The Blaskovics ptosis operation in the Moscow Eye Hospital. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 495.

Twenty-four operations convince the authors that the Blaskovics operation is the best one for ptosis and is indicated in all cases.

Ray K. Daily.

Kostenko, P. G., and Kopit, P. Z. The pathology of the lacrimal sac in trachoma. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 505.

A detailed report of the microscopic examination of 33 extirpated lacrimal sacs, nine of which were from cases of trachoma. The authors conclude that the microscopic picture of dacryocystitis in patients with trachoma has no characteristic features. (Photomicrographs.)

Ray K. Daily.

Michail, D., and Zolog, N. New research concerning the action of adrenalin on the lacrimal elimination of

glucose. *Bull. de l'Acad. de Méd. de Roumanie*, 1938, v. 5, no. 4, pp. 607-612.

The injection of adrenalin into the lacrimal gland alone or associated with a subcutaneous injection produces bilateral excretion of glucose in the tears, more apparent on the side on which the gland has been injected. Conjunctival instillation of adrenalin produces hyperglycemia but no lacrimal excretion of glucose, presumably because of reflex inhibition. The ability of adrenalin to cause lacrimal elimination of glucose is decreased in simple glaucoma. This becomes more apparent as the glaucoma approaches the absolute stage.

Saburov, G. I. A case of neurofibroma of the upper lid and nodules in the iris in Recklinghausen's disease. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 557.

A report of a case in a thirteen-year-old girl. A Blaskovics operation was performed for ptosis, without cosmetic result. Microscopically, between the epithelial and meibomian glands, the muscle and cartilage excised during the operation showed numbers of horizontal and vertical nerve strands. The enlargement of the nerve strands was caused by proliferation of the perineurium and endoneurium.

Ray K. Daily.

Subileau, J. Twin trephining in dacryorhinostomy. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 342-351.

The author modified a trephine instrument used by Arruga, so as to produce twin trephine openings, 9 mm. in diameter, in an operation for dacryorhinostomy. All the osseous surface corresponding to the lacrimal groove is removed, including the anterior and posterior crests. The edges of the bone

are smoothed off with bone forceps. No case reports are given.

Clarence W. Rainey.

Weeks, W. W. Ectropion and entropion of the eyelids. *Amer. Jour. Surg.*, 1938, v. 42, Oct., pp. 78-82.

The author outlines several of the classical procedures for the correction of ectropion and entropion and gives his opinion of each. The illustrations are an outstanding feature of this article. (5 figures, 3 references.)

Ralph W. Danielson.

Wheeler, J. M. The use of the orbicularis palpebrarum muscle in surgery of the eyelids. *Amer. Jour. Surg.*, 1938, v. 42, Oct., pp. 7-9.

The paper describes the use of the orbicularis in correcting congenital absence of the external canthal ligament, ptosis of the upper lid, and spasmodic inversion of the lower lid. (6 figures.)

Ralph W. Danielson.

Zikulenko, K. I. Egg white in ocular surgery. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 511.

The author substitutes hard-boiled egg-white for mucous membrane from the lip in marginoplastic surgery. His observations lead him to believe that the mucous membrane transplant merely serves as an obstruction to adhesion of the two opposing surfaces, and thus permits ingrowth of connective tissue. He finds that egg white acts as a hemostatic and adheres firmly to the cut surfaces. When the intermarginal area has become filled in with connective tissue the egg white is extruded.

Ray K. Daily.

TUMORS

Dupuy-Dutemps, Pierre. Radium therapy of meibomian epitheliomas.

Bull. Soc. Franç. d'Opht., 1938, v. 51, pp. 298-302.

The author reports the favorable results obtained in the treatment of two patients having meibomian epithelioma. The radium caused rapid disappearance of the local lesion, and swelling of the preauricular lymph gland. Surgical removal of the submaxillary lymph glands, followed by more radium, produced apparent cure, after four years observation.

Clarence W. Rainey.

Evans, P. J. Radon treatment of secondary carcinoma of the choroid, post-mortem observations. *Brit. Jour. Opth.*, 1938, v. 22, Dec., pp. 739-745.

This is the subsequent history of a case described by the author in 1937 (see *Amer. Jour. Opth.*, 1938, v. 21, Jan., p. 106), at which time the use of radon seeds in the treatment of secondary carcinoma of the choroid in a woman aged 41 years was reported. In 1937, treatment was being given the remaining eye, the first having been enucleated in January, 1936, for the same condition. During the major portion of the period here covered good vision was maintained, ultimate failure of vision being due to intracranial complications involving the optic nerve. In otherwise hopeless conditions, radon seeds may prove a worthy alternative to removal of the eye. Post-mortem findings are described in detail. (Figures.)

D. F. Harbridge.

Kalt, Marcel, and Tille, H. Symmetric lymphoma of the two semilunar folds, a symptom revealing lymphoid leukemia. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 364-372.

A 66-year-old man presented two kidney-bean-sized reddish tumors, one at each semilunar fold. The right tumor mass was removed surgically, and was

found to have the microscopic structure of a lymphoma. Other positive findings in the physical and laboratory examinations indicated leukemia of the chronic lymphoid type.

Clarence W. Rainey.

Koyanagi, Y. Tumor-like proliferation of the retinal pigmented epithelium in metastatic carcinoma of the choroid. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 732-742.

In a man 37 years old, with a primary carcinoma of the right lung, there occurred a metastasis in the choroid of the left eye, just around the optic nerve. Along the under side of the detached retina just internal to the choroidal carcinoma, was observed a membranous formation composed mostly of pigmented cells derived from the retinal pigmented epithelium. Numerous mitotic figures were present among these cells, but no connective tissue.

H. D. Lamb.

Lange, Helmut. Retinal glioma with special consideration of its heredity. *Klin. M. f. Augenh.*, 1938, v. 101, Dec., p. 854.

This is a report on 36 cases of retinal glioma observed in the last 22 years at the Halle eye clinic. Twenty patients, or 44.4 percent, are still living. Of patients with monolateral glioma, 76 percent were cured. The mortality of bilateral glioma is much higher. Tables show beginning of the disease at various ages from one to nine years. The investigations show that retinal glioma may be hereditary. In the hereditary cases it was bilateral. In the clinic glioma occurred in 0.0217 percent of all eye patients. Three cases are described in detail.

C. Zimmermann.

Oribe, M., and Mallbran, J. Anatomical and clinical consideration of retinal

glioma. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, June, p. 319.

The authors present a very comprehensive review of the historical background of retinal glioma, and report five cases. The gross and microscopic appearances of this group of tumors are described in detail, with their clinical behavior. The theories of rosette formation are quite fully discussed and also the analogy between certain tumors of the central nervous system and those occurring in the retina. The authors advance the hypothesis that there are three distinct varieties of retinal glioma. The first is a highly malignant type which they would designate as retinoblastoma and which is held to be analogous to medulloblastoma of the central nervous system. The second type, which is benign, is the retinocytoma. The analogous neoplasm of the nervous system is the astrocytoma. Third, there is a tumor of neuroblastic rather than glial origin. (Illustrated.)

Edward P. Burch.

Paiva, Aroldo. Malignant melanosis of the ciliary body. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, July, p. 363.

A case of malignant melanosarcoma of the ciliary body is reported by the author. After enucleation the sections were subjected to study, but the exact cell type of the neoplasm could not be determined. (Illustrations.)

Edward P. Burch.

Siegert, Peter. Melanosarcoma of the iris. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 591-639.

There are reported three cases of simple sarcoma of the iris in varying stages of development. In the first case, sarcoma cells have developed among the chromatophores of a pigmented nevus of the iris. The remaining two

cases are of flat, malignant pigmented tumors of the iris. In melanosarcoma of the iris, there frequently exists considerable discrepancy between the clinical and anatomic findings of malignancy. Such a growth may develop without producing any symptoms. On the other hand, even where a sarcoma of the iris causes loss of vision from glaucoma, no destructive growth or metastasis may exist. Roentgen raying does not appear to guarantee lasting results. Metastasis of the generally very slowly growing tumor apparently occurs along preformed tissue clefts and perivascular lymph spaces. Sarcoma of the iris may be considered with overwhelming probability to be of mesodermal origin. H. D. Lamb.

Susman, William. Intraocular tumors. *Brit. Jour. Ophth.*, 1938, v. 22, Dec., pp. 722-739.

There are essentially three types of intraocular tumor: retinal tumors of neural origin, sarcomata of the choroid with choroidal differentiation, and melanomata of the choroid. Retinal tumors may be designated as neuro-epithelioma, apolar spongioblastoma, polar spongioblastoma, neuroblastoma, and neurocytoma. Sarcoma of the choroid should be considered as malignant choroidoma. Melanomata are few by comparison and are designated by typical branched melanotic cells. Pigment is not diagnostic of a melanoma, as it may be present in many retinal tumors, its presence merely indicating that the growth has disturbed the choroid. The types of tumor are fully described, and results outlined. (Figures, tables, references.) D. F. Harbridge.

Teulières, M., and Beauvieux, J. Fibroma of the sclerotic. *Arch. d'Ophth.*

etc., 1938, v. 2, Dec., p. 1073; also *Bull. Soc. Franç. d'Ophth.*, 1938, v. 51, p. 372.

Examination of the right eye of a five-year-old boy disclosed a reddish, swollen, indurated roll of tissue occupying the entire cul-de-sac. Vision was 3/10 after the overlying conjunctiva was mobile. The mass was intimately attached to the eyeball (which was proptosed downward over the superior-rectus tendon). It was removed under local anesthesia. Diplopia disappeared and at the end of a few months the vision became normal. Pathologic examination showed a nonmalignant fibroma rich in blood vessels. (Illustration, references.) Derrick Vail.

16

INJURIES

Bruhn, A. M. Clinical and experimental investigations on eye lesions by burr hairs. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 730.

Eight cases of lesions by the pappus hairs of burrs in late summer at the time of maturity and opening of the burr baskets are described. The typical clinical picture consisted of loosening and papillomatous hypertrophy of the conjunctiva, especially the upper fornix, formation of pseudomembranes on the conjunctiva of the upper lid, and erosions and herpetic changes of the cornea. If the burrs remained they caused formation of granulomata. Introduction of burr hairs in the conjunctival sacs of animals produced similar conditions. Injection of oily extracts into the outer layer of the cornea showed no effect, but aqueous extracts produced violent reactions. Hence a chemical poison soluble in water is inferred, supplementing the mechanical irritation.

C. Zimmermann.

NEWS ITEMS

Edited by DR. H. ROMMEL HILDRETH
640 S. Kingshighway, St. Louis

News items should reach the Editor by the twelfth of the month

DEATHS

Dr. Walter Lewis Horn, New York City, died December 29, 1938, aged 47 years.

MISCELLANEOUS

The National Society for the Prevention of Blindness has announced that it is coöperating with the following colleges and universities in offering, at their 1939 summer sessions, courses for the preparation of teachers and supervisors of sight-saving classes:

Western Reserve University, Cleveland, Ohio, June 19th to July 28th. Director of the course, Miss Olive S. Peck, Supervisor, Braille and Sight-Saving Classes, Board of Education, Cleveland, Ohio.

State Teachers College, Buffalo, New York, June 26th to August 4th (dates tentative). Director of the course, Miss Agnes Reuter, Department of Special Education, Buffalo Public Schools, Buffalo, N.Y.

State Teachers College, Milwaukee, Wisconsin, June 26th to August 4th. Director of the course, Miss Marguerite L. Kastrup, Supervisor of Braille and Sight-Saving Classes for Northern Ohio, Cleveland, Ohio.

University of California, Los Angeles, California, June 26th to August 4th. Director of the course, Miss Frances Bland, Principal of Sight-Saving Classes, Los Angeles City Schools, Los Angeles, California.

Wayne University, Detroit, Michigan, June 26th to August 4th (elementary and advanced courses). Director of the elementary course, Mrs. Gladys Dunlop Matlock, Detroit, Michigan. Director of the advanced course, Mrs. Winifred Hathaway, Associate Director, National Society for the Prevention of Blindness, New York, N.Y.

Details regarding the courses may be obtained from the university or college, or from the director in charge of the course.

SOCIETIES

The mid-year meeting of the North Dakota

Academy of Ophthalmology and Otolaryngology was held at Fargo, February 11th. Dr. Avery D. Prangen of the Mayo Clinic, as guest speaker, addressed the group on "Some fundamental problems of refraction."

The Eye Section of the Philadelphia County Medical Society presented the following program on March 2d: The optic atrophy in pituitary disease, by Dr. M. W. Thorner; Pathology of the subchoroida with microscopic projection, by Dr. Perce DeLong.

"The American Physicians' Art Association composed of members in the United States, Canada, and Hawaii, will hold its second Art Exhibit in the City Art Museum of St. Louis, May 15 to 20, 1939, during the annual meeting of the American Medical Association. Art pieces will be accepted for this art show in the following classifications: (1) oils both (a) portrait and (b) landscape; (2) water colors; (3) sculpture; (4) photographic art; (5) etchings; (6) ceramics; (7) pastels; (8) charcoal drawings; (9) book binding; (10) wood carving; (11) metal work (jewelry). Practically all pieces sent in will be accepted. There will be over 60 valuable prize awards. For details of membership in this Association and rules of the Exhibit, kindly write to Max Thoreck, M.D., Sec'y, 850 Irving Park Blvd., Chicago, Ill., or F. H. Redewill, M.D., Pres., 521-536 Flood Bldg., San Francisco, Calif."

The Los Angeles Society of Ophthalmology and Otolaryngology announces the following officers for 1939: President, Dr. Pierre Viola; Vice-President, Dr. Henry B. Lemere; Secretary-Treasurer, Dr. John P. Lordan; Committeeman, Dr. M. N. Beigelman. Meeting place, Los Angeles County Medical Association Building, 1925 Wilshire Blvd., Los Angeles. Time, 6:00 p.m., fourth Monday of each month from September to May, inclusive.

SPASTIC-ENTROPION CORRECTION BY ORBICULARIS
TRANSPLANTATION*JOHN M. WHEELER, M.D.
New York

Many procedures have been suggested for the correction of spastic entropion of the lower eyelid. Most of them depend for their effectiveness on a downward pull, calculated to unroll the inverted lower lid, and, by downward traction, to prevent turning in of the margin. Such pull may be accomplished by the application of adhesive plaster, by the insertion of buried sutures, as suggested by Snellen, Gaillard, Arlt, and others, or by making skin excisions, as proposed by Celsus, von Graefe, Janson, Panas, and many other writers. Skin and subcutaneous-tissue contraction, effected by means of acid and by the application of the actual cautery, has been recommended, and the use of the cautery has been stimulated in recent years by Ziegler's advocacy of his method.¹

Not quite all the procedures for correction of spastic entropion are dependent on methods that induce downward pull on the lower lid. For example, Pochisov² advises canthotomy and severance of the attachment of the outer part of the eyelid to the orbital margin. Goldzieher³ and Blaskovics⁴ removed a triangle of skin from the zygomatic region, and so made lateral traction on the skin of the lower eyelid. Alfred Vogt⁵ suggested a free canthotomy and a readjustment of the

flaps between the outer canthus and the orbital margin, so that during the healing process the lower flap is held forward slightly by the sutures. The result of the maneuver is that the outer part of the lower lid is held slightly away from the globe. In 1929 Valiere Vialeix⁶ advocated excision of the upper part of the epitarsal orbicularis of the lower lid. In 1931 Hughes⁷ described a technique for weakening the action of the orbicularis by the injection of 95-percent alcohol into the muscle near the outer canthus. The use of alcohol has been recommended by other observers. Weekers⁸ found that entropion had recurred in some patients who had received alcohol injection into the lower lid, and hence he advised, for cases in which the condition had existed for some time, a combination of alcohol injection and canthotomy.

I have been unable to find any reference to an operation resembling the one I describe here, unless it be the procedure credited to Birch-Hirschfeld, which is illustrated in the volume on surgery of the eye just published by Blaskovics and Kreiker. In that operation orbicularis strips are dissected up and are tied by sutures that pass through the skin of the eyelid.⁹

In January, 1935, I first performed the following operation:

OPERATION

Anesthesia.—Infiltration of the opera-

*Presented at the Seventy-fourth Annual Meeting of the American Ophthalmological Society at San Francisco, California, June 9-11, 1938.

Fig. 1 (Wheeler). Skin incision. For the sake of clarity the lid margin is shown in normal position, instead of in entropion.

Fig. 2 (Wheeler). A strip of orbicularis muscle about 4 mm. wide is dissected and its free end is held by a suture. The nasal end of the strip is left attached a little below the tarsus. An incision in the orbicularis has been carried over the zygomatic (malar) bone.

Fig. 3 (Wheeler). Skin and orbicularis flaps are retracted to expose the periosteum, and the strip of orbicularis is attached to the periosteum in its advanced position. The strip is taut.

tive field with a 1-percent solution of novocaine (with or without adrenalin) produces satisfactory anesthesia. The magnification of the tissues that results from infiltration, with increase of the

tissue bulk, makes the dissection easier and enables the surgeon to work with greater accuracy than is possible without infiltration. The injection of fluid into the tissue in front of the tarsus and tarso-

orbital fascia eliminates the entropion, and leaves the lid in good position during the operation.

The primary skin incision is begun about 6 mm. from the lower lid margin, a little nasalward of the center of the eyelid, and is carried in the direction of the lid margin into the zygomatic (malar) region, about 1 cm. beyond the orbital margin (fig. 1). The skin is then dissected from the orbicularis above and below the incision.

A strip of orbicularis muscle about 4 mm. wide is dissected free just below the lower border of the tarsus, with a cut end at the outer orbital margin. This strip is left attached at its nasal end at a point a little beyond the center of the lower lid (fig. 2). Next the orbicularis is divided over the zygomatic (malar) bone by an incision passing outward and upward, and the orbicularis flaps are separated so as to expose the periosteum (fig. 3).

The strip of orbicularis is put on the stretch and attached to the periosteum. It is sutured to its new position by two 000-chromic-catgut sutures, as shown in figure 3. It should be observed that the end of the orbicularis-muscle strip is carried not only temporalward but also upward, and that the muscle strip is thoroughly taut. As the dissection is a little below the tarsus, and so is not attached to it, the lid margin is not pulled much out of place laterally, but the lower lid does receive support.

The skin wound is closed by fine silk sutures, either with interrupted ties or by means of a single subcutaneous suture. I like the security and accurate apposition given by the interrupted sutures, carried through the flaps very near their cut margins.

The eyelids are covered by a protective tissue, such as gutta-percha, with a thin

Fig. 4 (Wheeler). Photograph of a patient who had bilateral spastic entropion of the lower lids. The right lower lid was treated by excision of the skin with orbicularis and repeated cautery punctures. On the left lower lid the orbicularis-strip-advancement operation was performed. Note the lowered position of the right-lower-lid margin, and the normal position of the left-lower-lid margin.

smear of vaseline. A gauze dressing is applied, secured by adhesive plaster, and over this a snug bandage is placed. The dressing should be left on for from five to seven days. After this the skin sutures can be removed and the dressing reapplied, to be left in place for a day or two, by which time the skin wound will have healed, and the transplanted muscle strip be securely adherent to the periosteum.

The result of this procedure is permanent correction of the spastic entropion without appreciable scarring or other disfigurement. The lid is well supported by

Fig. 5 (Wheeler). Correction of spastic entropion by shortening the orbicularis just below the tarsus of the lower eyelid. Skin incision.

the attachment of the muscle strip, so that the lid margin is in normal position. Such a result is in contrast to that obtained by skin excision, buried sutures, or cautery scars, which usually fail to have a permanent effect and which pull the lower-lid margin downward out of proper place.

Figure 4 shows comparative results in a patient on whom different methods were used for the two lower eyelids. On the right side, skin with orbicularis excision was performed once, and the caut-

ery-puncture procedure was employed four times. Repeated operations were needed on account of recurrences of the spastic entropion. On the left side, the orbicularis-strip advancement was performed. Although the five procedures finally corrected the entropion of the right lower lid, they pulled the lid margin down out of place. On the other hand, the orbicularis advancement not only corrected the entropion in one maneuver but gave the lid margin good support, so that it is at the normal level.

Fig. 6 (Wheeler). Correction of spastic entropion by shortening the orbicularis just below the tarsus of the lower eyelid. The skin is dissected up and the skin flaps are held in retractors. A strip of orbicularis muscle is dissected and held on a strabismus hook.

Fig. 7 (Wheeler). A double-armed suture has been carried through the tarso-orbital fascia below the tarsus and through each orbicularis flap 4 mm. from its end.

This operation was performed successfully in several cases and can be thoroughly recommended; nevertheless, about a year ago it occurred to me that a similar result might be obtained in a simpler way, and I offer as a useful alternative the following procedure that I then adopted:

An incision is made in the lower lid, about 5 mm. from the margin, extending nearly the whole length of the lid (fig. 5). Above and below the incision the skin is dissected from the orbicularis, and a

strip of orbicularis muscle 4 mm. wide is dissected up, as shown in figure 6. This strip is taken from the muscle just below the lower border of the tarsus. It is cut in the center, but left attached at the ends. Then a 000 catgut suture is carried through the tarso-orbital fascia about 2 mm. below the tarsus. It is next carried through first one flap of the orbicularis strip and then through the other, so as to force an overlapping of 4 or 5 mm. (fig. 7). The suture is then tied, and the overlapping is made secure by

Fig. 8 (Wheeler). The overlapping of the orbicularis flaps is secured by 000-catgut sutures, and the shortened strip is held in position just below the lower border of the tarsus.

two additional catgut sutures, as shown in figure 8. The skin wound is closed and a secure dressing is applied.

With this method the results have been favorable, but in the first two cases in which I operated there was overcorrection as a result of the orbicularis strips causing too much pressure at the border of the tarsus. In these cases the overaction of the operation, with its resultant

ectropion, was corrected by the use of cautery puncture on the conjunctival surface of the lids. After repeated trials I decided that an overlapping of 4 to 5 mm. seemed to be right.

This simple procedure can be recommended, but the operator must bear in mind the possibility of overcorrection or undercorrection.

DISCUSSION

DR. EDWARD JACKSON, Denver: Dr. Wheeler has introduced us to a somewhat new field of lid surgery. I would like to ask if there is any difficulty in isolating the portion of orbicularis that is required.

DR. JOHN E. WEEKS, Portland, Oregon: I have been very much interested in Dr. Wheeler's description of the operation that he has introduced and have no doubt that the results following this procedure are excellent. For many years I have employed a simple operation for the correction of spasmodic entropion, which is described and illustrated in my treatise, "Diseases of the eye."* Nearly all, if not quite all, cases of spastic entropion exhibit a redundancy of tissue in the lower lid on the side affected. By following the technique that I have described, the redundant tissue is removed, the appearance of the patient is improved, and the entropion is permanently corrected—at least

I have seen no return of entropion in the cases I treated. I have employed multiple puncture by the cautery, the Gaillard suture, and other procedures, but have abandoned them all in favor of the simple operation referred to.

DR. RAMON CASTROVIEJO, New York: Dr. Jackson has asked whether it is difficult to isolate the fibers of the orbicularis in performing Dr. Wheeler's operation for the correction of spastic entropion of the lower eyelid. I should like to answer this question for Dr. Wheeler, since it will be more effective if the answer is given by some one who has not had the wide surgical experience and does not possess the skill of Dr. Wheeler. I have had the opportunity in one case of performing the operation that Dr. Wheeler has illustrated today. I did not find it difficult to isolate the fibers of the orbicularis, and the entropion was permanently corrected.

*Weeks. Diseases of the eye. Philadelphia, Lea and Febiger, 1910, p. 786.

In another case of entropion of the

upper lid I had planned to remove a strip of tarsus, but when novocaine was injected for local anesthesia, the entropion corrected itself. I thought then of Dr. Wheeler's operation for the spastic entropion of the lower lid, and a similar operation was performed on the upper lid of the patient. The entropion in this second case has been permanently corrected. It would be good judgment to keep Dr. Wheeler's operation in mind, since it could be performed in some cases of entropion of the upper lid.

DR. JOHN M. WHEELER, closing: I wish to thank Dr. Jackson, Dr. Weeks, and Dr. Castroviejo for their discussion of the paper. Dr. Castroviejo has partly answered Dr. Jackson's question. I do not know exactly what Dr. Jackson had in mind, but my technique has been something like this: to inject the lower lid

thoroughly with novocaine, so as to secure good magnification of the fibers, and to reduce the entropion while the operation is going on. In the second procedure I spoke of, it is perfectly feasible to clamp the lid so that there will be no hemorrhage. In the dissection one is almost sure to divide the palpebral arteries, and they must be clamped in the dissection. I prefer to leave the orbicularis in place, and with the scissors cut down against the tarsus against which the strips are outlined, and then, lifting the outlined strips with a pair of forceps, cut under with very fine scissors; in this way it is easy, by holding the strip on a hook, to carry on the dissection toward the ends of the lids. The sutures are placed in such a way that one can be sure of the accurate overlapping and the position of the tightened orbicularis strips.

LECTURES ON MOTOR ANOMALIES*

IX. OCULOMOTOR-NERVE PARALYSIS AND OPHTHALMOPLEGIAS

A. BIELSCHOWSKY, M.D.

Hanover, New Hampshire

Palsy of individual muscles governed by the third nerve is rare in comparison with that of the sixth and fourth nerves. One can dispense with a detailed description, since the signs and symptoms and the principles of the diagnostic analysis are to be derived from what has been

Fig. 34 (Bielschowsky). Isolated paralysis of the right inferior oblique muscle. Both eyes can be moved equally up and to the right (A), while in looking up and to the left (B) the right visual line cannot be raised above the horizontal plane.

said about abducens- and trochlear-nerve palsies.

Isolated paresis of the *inferior oblique* muscle is an extremely rare occurrence. The diagnosis of a total paralysis of the muscle as it is shown in figure 34A and B is easily made. In the primary deviation of gaze the paretic eye is deviated downward. In looking down there is no deviation at all and perfect binocular single vision. In supraversion the right eye lags behind. In looking up and to the right the elevation of both eyes is apparently equal, whereas in looking up and to the left the right visual line cannot be raised above the horizontal plane. From this it

must be concluded that the right inferior oblique is totally paralyzed, because that muscle plays the main part in elevating the averted visual line. Figure 35 shows the field of fixation taken by means of after-images. The lighter-dash line represents the limits of the left field of fixation; the heavier-dash line, the limits of the right field of fixation. Both lines almost coincide both in the lower and in the right periphery. The upper limits meet only in the right upper corner. In the left periphery the right visual line cannot be raised even to the horizontal plane. The same behavior is demonstrated by the diplopia test (fig. 36): binocular single vision in the right periphery as well as in the lower half of the field of fixation, except in the left corner of the lower periphery. In the right upper corner there is almost no vertical distance between the double images but a marked obliquity, whereas in the left upper corner they show the maximum degree of vertical divergence, but no obliquity, because the oblique muscles have no influence on the vertical movement of the averted visual line; they have no influence on the position of the meridians—that is, on the torsion movement—while the eye is turned inward. If the patient's head is tilted toward the left shoulder, both the separation and the obliquity of the double images show the maximal degree, while by tilting it in the opposite direction binocular single vision is restored. The lateral separation of the double images is immaterial, because the loss of the averting component of the oblique muscles cannot manifest itself if it is compensated by a nonparetic exophoria.

* From the Dartmouth Eye Institute, Dartmouth Medical School. Read before the Seventh Annual Mid-Winter Clinical Course of the Research Study Club, Los Angeles, California, January, 1938.

Fig. 35

Fig. 35 (Bielschowsky). Field of fixation taken by means of afterimages in a case of total paralysis of the right inferior oblique muscle. The light-dash line represents the limits of the left field of fixation, the heavy-dash line the limits of the right field of fixation; the unbroken line separates the area of binocular single vision (down and right) from the area in which diplopia exists (up and left).

Fig. 36 (Bielschowsky). Double images of a horizontal object in a paralysis of the right inferior oblique.

Fig. 36

Isolated paresis of the *superior rectus* muscle is more often met with. In the majority of these cases it is of congenital origin, frequently combined with ptosis. The vertical divergence increases in elevation and in looking to the paretic side, since the superior rectus plays the main part as the elevator of the abverted visual line, which coincides with its muscle plane if the eye is turned out at an angle of 27 degrees. Figure 37 shows the double images in the field of fixation in a paresis

of the left superior rectus muscle. Figure 38A to D demonstrates the deviation in the different positions of the eyes. As a rule, the slight horizontal separation points to the loss of the adverting component, but is immaterial as in all the pareses of vertical motors. The head tilting test does not give such unequivocal clues for the diagnosis as it does in paresis of the oblique muscles.

A habitual position of the head will be met with if it helps the patient to see

Fig. 37 (Bielschowsky). Double images of a horizontal object in paralysis of the left superior rectus muscle.

Fig. 38 (Bielschowsky). Paralysis of the right superior rectus. While the left eye is looking straight ahead, the right eye is deviated downward (A). In looking up, the right eye lags behind (B). In looking up and to the right the visual line cannot be raised above the horizontal plane (C). Both eyes are equally moved up and to the left (D).

single. The head is either tilted backward or turned to the paretic side, so that the paretic eye is either turned down or in while an object straight ahead is looked

Fig. 39 (Bielschowsky). Double images of a horizontal object in paralysis of the right inferior rectus.

at. Which of these positions is chosen by the patient depends on the intensity of the paresis.

Isolated paresis of the *inferior rectus* is not infrequently due to traumatic lesions of the muscle. Figure 39 shows the double images in a typical paresis of the right inferior rectus. What was said before in the description of pareses of the other vertical motors applies, necessary changes being made, to that of the *inferior rectus*.

Paresis of the *internal rectus* demands special consideration. The internal rectus is the only muscle acting not only in parallel (lateroversion) but also in non-parallel (convergence) movements at the command of the will. Both functions, as well as only one, may be lost according to the site of the lesion. A loss of both functions without paresis of other muscles governed by the third nerve is very rare. Apart from peripheral injuries an isolated paresis of the internal rectus points to a lesion of its nucleus or the roots of its nerve, neither of which can be easily damaged without involving other ganglion cells or other roots of the third nerve. The clinical signs and symptoms of the paresis of the internal rectus show a behavior exactly contrary to that of abducens pareses: A habitual turning of the head toward the sound side; divergent deviation increasing when looking to the sound, decreasing when looking to the other, side; crossed diplopia, and so on. But there is one characteristic which is hardly ever found in any other paresis of a single ocular muscle. Most patients with a paresis or even a complete paralysis of the internal rectus are able to overcome the paretic divergence in the primary direction of gaze by means of a conver-

gence innervation, the only fusion innervation that is governed by the will. That is particularly striking in cases in which the maximum innervation for latero-version fails to turn the paretic eye beyond the middle position toward the nose. But a convergence impulse is able to bring the paretic eye from an extremely divergent into the middle position, so that the parallelism of the visual lines will be restored and a distant object lying in the median plane of the head will be fixated binocularly. This movement of the paretic eye takes place without any coöperation from the paralyzed muscle. According to the law of the reciprocal innervation that was established by Sherrington, the antagonist of a paralyzed muscle—that is, the external rectus—must relax even if the paralyzed internal rectus does not respond to an innervation impulse. Since the divergent position in our case is brought about by the tonus of the external rectus, the eyeball will move after the relaxation of the latter toward its mechanical position of rest; that is, as a rule, to the middle position. Considering the innate association of accommodation and convergence, one would expect an increase of refraction to take place if the paretic divergence is overcome by a voluntary convergence impulse. Indeed, patients with a certain range of accommodation will notice that the outlying objects appear blurred if the divergence is transformed into parallelism by a voluntary impulse. But within a few seconds the vision becomes clear again, due to a relaxation of the accommodative surplus after the fusion tendency has assumed the maintenance of the increased convergence innervation which, as long as it was maintained by the will, was accompanied by a corresponding amount of accommodation.

Paresis of the *levator palpebrae* is rather frequently the earliest and some-

times the sole permanent sign of a lesion of the third nerve. It is easily distinguished from the sympathetic ptosis which, as a part of the Horner syndrome, is combined with a contracted pupil and a slight enophthalmos. Sympathetic ptosis is always incomplete and the pupil cannot be dilated by stimulating the sympathetic dilator iridis with cocaine. Spastic (pseudo-) ptosis, caused by a contraction of the palpebral portion of the orbicularis muscle, may be mistaken for paralytic ptosis, particularly if it is unilateral and not connected with epiphora and photophobia; it occurs as a professional neurosis—for instance, in watchmakers—or as a hysterical sign, or in malingersers. The spastic origin is recognized either by the resistance to the passive raising of the upper lid or by its flickering and trembling movements, moreover by the wrinkles of the skin of the lid, the lower position of the brow, and the raised position of the lower lid.

Voluntary closure of the lids is accompanied, as a rule, by an involuntary upward movement of the eyeballs. The diagnostic value of this so-called Bell's phenomenon will be discussed presently. Under normal conditions the vertical movements of the eyes are associated with the movements of the upper lids, both taking place in the same direction; in looking up the lids are raised, in looking down they are lowered. In exophthalmic goiter this synergy is disturbed rather frequently, inasmuch as the upper lids lag behind while the gaze is being lowered (Graefe's phenomenon). This is due to an increased tonus of the levator palpebrae muscles. We are at present more interested in the disturbances of the synergy, under discussion occurring in the course of oculomotor pareses. A rather frequent and rather striking disturbance is called the pseudo-Graefe phenomenon, because it has a superficial

Fig. 40 (Bielschowsky). Pseudo-Graefe phenomenon as a residue of right oculomotor paralysis. A shows a slight anisocoria in the primary position as the only sign of the previous paralysis. B shows considerable dilatation of the pupil of the right eye in dextroversion. C, the upper lids are in equal position in looking down and to the right. D, striking retraction of the upper lid of the right eye (pseudo-Graefe phenomenon) and narrowing of the pupil of the right eye in looking down and to the left.

similarity to the true Graefe's phenomenon. The photographs of some such patients show different types of the phenomenon.

1. A man, 30 years of age, acquired paralysis of the right third nerve through a fracture of the base of the skull. Three months after the accident, I found as the only residues of the paralysis that the right pupil was moderately dilated, the light reaction was reduced to a minimum (fig. 40A to D), the convergence reaction was nearly normal, and there was a slight paresis of the superior rectus muscle. In the primary position the eyes were

parallel; the upper lids were equally high (fig. 40A). In looking down and to the right both the upper lids accompanied the eyes normally (C), whereas in looking down and to the left the right upper lid was retracted and the right pupil narrowed, so that the anisocoria disappeared (D).

2. A woman, 28 years of age, had total right oculomotor paralysis, the origin of which was not determined. Five months later she presented the signs demonstrated by the photographs (fig. 41A to D). The case differs from the previous one in that the upper lid did not go down at all either in looking down or in looking down and to the right. Probably this difference was due to the fact that the depressor muscles had recovered less in this case than in the others. But a true retraction of the right

Fig. 41 (Bielschowsky). In the primary position (A) dilatation of the pupil of the right eye is the only sign of the previous right oculomotor paralysis. In B and C the right upper lid remains unmoved when the impulse to look down or down and to the right is given. There is striking retraction of the right upper lid while the patient is looking down and to the left (D).

Fig. 42 (Bielschowsky). A shows left oculomotor paralysis, with the left upper lid completely relaxed. In B, a maximum contraction of the left superior oblique prevents the left eye from reacting to the elevation impulse, the left upper lid being raised considerably. In C, maximum innervation of the depressor muscles causes a slight lifting of the upper lid. D shows the levoversion impulse, with complete relaxation of the left upper lid. E shows, as an effect of the dextroversion impulse, maximum retraction of the left upper lid.

upper lid took place only in looking down and to the left. The right pupil behaved exactly as in the other case.

3. A student had total paralysis of the left third nerve as a result of a fracture of the base of the skull. The most inter-

esting sign of the paralysis in its first stage was the enormous contraction of both left depressor muscles, chiefly of the superior oblique, which was especially impressive when the patient was looking up (fig. 42A to E). The left eye appeared stationary, while the right eye was looking straight ahead, to the right, down, or up. Only in looking to the left was there a moderate abversion of the left eye with the same degree of depression.

The patient was under my observation for more than three years. Not until 15 months after the fracture was the first change noticed. In the left upper lid which, hitherto, had been completely relaxed, some folds appeared, and while looking straight forward the patient was unable to lift the lid more than 3 mm. by a maximum effort. On looking to the left

Fig. 43 (Bielschowsky). A shows total left ophthalmoplegia. The elevation impulse does not influence the left upper lid (B). C shows a slight lifting of the upper lid of the left eye in dextroversion. In D, the left upper lid goes up while the patient is looking down (head thrown back).

the lid became completely relaxed and could not be raised at all, whereas when a strong impulse for looking down was given it rose a few millimeters automatically; this retraction was greater when the right eye looked up; a maximum retraction of the left upper lid was found in connection with the impulse to look to the right.

4. A woman, 35 years old, had basal syphilis, which had caused atrophy of the left optic nerve, paralysis of the left fifth nerve, and total left ophthalmoplegia. The left eye was immovable (fig. 43A to D). The left upper lid could not be raised by the strongest effort; it remained relaxed even when the patient looked up (B), but when she looked to the right it rose automatically a little (C), and in looking down it rose still more (D), concurrently with the arrival of the normal right upper lid at its lowest position.

E. Fuchs explained the so-called pseudo-Graefe's phenomenon as follows: Because the third nucleus is injured, or has become atrophic in consequence of a retrograde degeneration, the nervous stimulation sent to a part of the third nucleus extends over the neighboring parts, so that unintended, together with intended, movements are obtained. In my opinion, this theory cannot be reconciled with the following facts: First, there are patients who display the retraction movement of the upper lid in spite of the fact that all the exterior ocular muscles have lost their function completely and the levator palpebrae reacts only automatically to impulses sent to certain other muscles, especially the depressors, which have no physiologic (functional) connections with the levator palpebrae. Further, in nearly all of my patients who showed the phenomenon under discussion the paralysis of the third nerve must have been located at the basis cranii. Either there had been a basal fracture or the

symptoms additional to the third-nerve paralysis necessitated that localization. I cannot imagine a complete retrograde nuclear degeneration, as Fuchs supposed, in which only the nucleus innervating the levator muscle is spared and even this nucleus is not capable of being stimulated voluntarily but responds only to impulses sent to some other atrophic parts of the third nucleus.

I think that the pseudo-Graefe sign can be explained in a less far-fetched manner. Suppose that the continuity of the third nerve is interrupted by a trauma or a tumor. In the course of healing some of the fibers which proceed from the central part of the trunk of the third nerve do not find their original sheaths in the peripheral part of the nerve but go astray, so that they arrive at muscles to which they do not belong. For instance, the fibers from the nucleus intended for the internal rectus arrive not at this muscle but at the levator of the upper lid, so that the impulse for adversion produces lifting of the upper lid, even if it cannot be lifted by a direct innervation effort because the fibers coming from the levator nucleus have gone astray. In some cases a part of the nerve fibers intended for the levator arrive at this muscle together with fibers of a different origin, so that there is no ptosis but an abnormal retraction of the upper lid as soon as an impulse is sent to certain other eye muscles. It seems that the nerve fibers in the course of healing prefer certain "routes" for growing in the wrong sheaths, so that in the majority of cases the impulse to look down and in produces the strongest contraction of the levator of the upper lid.

Another interesting lid phenomenon is the so-called sign of Marcus Gunn, or jaw-winking (fig. 44A to D). In most of these cases there is unilateral congenital ptosis, sometimes combined with paresis of other muscles supplied by the third

Fig. 44 (Bielschowsky). Jaw-winking phenomenon. Congenital ptosis and paralysis of the elevator muscles of the left eye (A). The left upper lid can be raised neither voluntarily nor in looking up (B), but is retracted involuntarily when the mouth is opened (C) or the jaw is moved to the right (D).

nerve, mostly the superior rectus, and in only a few cases is ptosis absent. The photographs show an example of the jaw-winking phenomenon. There is a moderate congenital ptosis of the left upper lid, which can no more be raised by a voluntary innervation of the levator palpebrae than it can in looking up. But if the mouth is opened or the jaw is moved to the right there is a striking involuntary retraction of the left upper lid. It drops down while the jaw is moved to the left. In some cases these unilateral movements of the upper lid are connected with the act of sucking or swallowing. The jaw-winking phenomenon is generally explained by assuming that in such cases the nerves supplying one of the levators originate in that part of the fifth nerve which also supplies the jaw muscles, particularly the external pterygoid muscle.

Without discussing the well-known signs and symptoms of the total paralysis of the third nerve, I would mention only a few unusual and interesting phenomena that occur in some of these cases. Rather frequently there is a marked exophthalmos due to the loss of the retracting component of nearly all the eye muscles. Occasionally one will find a striking retraction movement of the protruding eye

when turned out. That the exophthalmos is responsible for the retraction movement in those cases must be inferred from the fact that both disappear at the same time, while the paralyzed nerve regains its function.

A rare phenomenon, called "nystagmus retractorius" by Körber,¹ who first described it, may be mentioned because of its topical diagnostic value. It has been observed only in cases of grave injury of the nuclear region between the third and the fourth ventricle, either diagnosed by the characteristic paretic signs and symptoms of indubitably nuclear origin or substantiated by autopsy. Elschnig's² case was caused by a cysticercus vesicle in the third ventricle; other cases have been due to tumors of this region. Besides paresis of a few or many muscles of both eyes, the most striking sign is a retraction of one or both eyes following every impulse sent to the ocular muscles. Elschnig has explained this phenomenon as follows: The compression of the whole nuclear region and all its connections, especially the posterior longitudinal bundle, causes disturbance of such kind that every motor innervation not only excites the ganglion cells that are responsible for the intended movement but spreads over the whole nuclear region, thus bringing about the

simultaneous contraction of all the external ocular muscles and the consequent retraction movement.

If the paralyzed eye is constantly fixating because of ametropia or amblyopia of the other eye, the secondary deviation can assume really grotesque forms. Figure 45A to C shows total bilateral oculomotor paralysis with the right eye

a contraction of the latter taking place when the lids are closed forcibly. This peculiar behavior of the pupil, which has been observed even in cases in which the paralysis of the third nerve was due to a lesion of the trunk, has not yet been explained satisfactorily. It would be easily understood by the assumption that the nerve supplying the sphincter iridis

Fig. 45 (Bielschowsky). Total bilateral oculomotor paralysis. Right eye is fixating (A) while the cornea of the left eye is hidden behind the external angle of the palpebral fissure as a consequence of the enormous contraction of the left external rectus (B). The cornea of the left eye is revealed by a strong dextroversion impulse (C).

fixating. The left eye is hidden behind the external angle of the palpebral fissure as a consequence of the enormous contraction of the left external rectus. The cornea of the left eye is revealed only by a strong dextroversion impulse.

In total oculomotor paralysis the pupil is dilated and the reaction to light as well as to the convergence impulse is missing. During recovery the convergence reaction is quite frequently restored earlier than the reaction to light. There are many cases in which, after the exterior muscles have regained their function, the pupil remains more or less dilated while the convergence impulse, though somewhat sluggish as a rule, shows a fairly normal range in contrast to the complete absence of the light reaction which, in quite a number of cases, never returns. In most of them there is also to be found a very striking orbicularis phenomenon of the pupil; that is,

has two roots either of which could be damaged separately. The fibers bringing about the convergence reaction might be more resistant than those responsible for the light reaction, so that they also recover more quickly and more completely. But there is as yet no anatomic proof of such a hypothesis. In some of the cases with the aforementioned pseudo-Graefe phenomenon the involuntary reaction of the upper lid is accompanied by an isolated contraction of the pupil which otherwise showed either normal or a sluggish or no reaction to light at all. This pupillary phenomenon must be explained in the same way as that of the upper lid, by assuming that some of the oculomotor fibers, after the trunk had been interrupted by some lesion or other, do not find their original sheaths in the peripheral part of the nerve but go astray, so that some of the fibers intended either for the internal or the inferior rectus,

Fig. 46 (Bielschowsky). Cyclic right oculomotor palsy combined with abducens palsy. A shows the paralytic phase: complete ptosis, the pupil of the right eye dilated maximally. During the spastic phase the right palpebral fissure is opened and the pupil of the right eye narrowed maximally (B). The levoversion impulse elicits the spastic phase (C); dextroversion, the paralytic phase (D). Equal position of the upper lids in looking down during the paralytic phase (E); pseudo-Graefe phenomenon during the spastic phase (F).

but arriving at the sphincter iridis, may cause a contraction of the pupil when the patient gives an impulse for in- or downward movement. Very interesting are some observations of total oculomotor paralysis in which all the pupillary reflexes are apparently completely abolished but a prompt contraction of the pupil takes place if an abversion impulse is given, a behavior which points to a congenital anastomosis between the abducens nerve and the ciliary ganglion.

The most peculiar features are presented by the cases of so-called *cyclic oculomotor palsy* (Axenfeld), the principal characteristic of which is the automatic alternation of spastic and paralytic conditions of the paretic eye (fig. 46A to F).

According to his mother the patient was born with normal eyes. When he was one year old the right upper lid gradually drooped. In 1920 he was brought to Uhthoff's clinic, where right oculomotor paralysis and right abducens-nerve paresis were noted and a ptosis operation was performed. I saw the boy eight years later and noted the automatic alternating spastic and paralytic conditions. In the latter phase there was a nearly complete ptosis in spite of the previous operation (A). The right pupil was dilated maxi-

mally and was rigid. When the patient was left to himself staring into vacancy, one could observe after a fraction of a minute a little twitch arising in the paralyzed upper lid, gradually becoming quicker and livelier and finishing with a complete opening of the palpebral fissure. At this moment the right pupil, which before had been dilated, would contract to the minimum size while the left pupil kept its normal size unchanged (B). After 10 or 20 seconds the right upper lid would go down slowly, and at the same time the right pupil would dilate again. This cycle repeated itself at irregular, but mostly very short, intervals all day and all night, provided the patient did not make voluntary eye movements of great extent. The influence of voluntary movements is shown by the subsequent photographs. When the boy was ordered to look to the left during a spastic phase (C), this phase would remain as long as the patient maintained the levoversion. If the order was given during a paralytic phase, this phase would be interrupted after a few seconds and replaced by the spastic phase. The contrary effect was obtained by the antagonistic voluntary innervation. As soon as an impulse for dextroversion was given, the pupil of the right eye would dilate and

the upper lid would droop (D), the condition persisting as long as the boy looked to the right. The last photographs show the position of the right upper lid in looking down during a paralytic (E) and during a spastic (F) phase. The latter gives an impression of the pseudo-Graefe phenomenon.

When I collected the case reports of so-called cyclic oculomotor paralysis, I found altogether 32; having seen 10 cases myself, I am convinced that the condition is not so rare as the small number of published cases would lead one to suppose. There are rudimentary forms of the phenomenon which in the example cited was rather fully developed. Only the pupil of the paralyzed eye has shown the cyclic type of paralysis in all the cases observed by me and reported by others. In one third of the cases the upper lid did not participate in the cyclic phenomenon. Cases in which the internal rectus muscle shared in the cycle are fewer still, and it is exceptional to find the inferior rectus actively involved. The elevator muscles never participate in the alternating spasms and relaxations. So it is easily understood that mild cases, presenting perhaps only the phenomenon of automatically alternating dilation and contraction of the rigid or apparently paralyzed pupil, are overlooked. Some of them have been reported as cases of third-nerve paralysis showing a peculiar pupillary phenomenon. In about 50 percent of the cases the phenomenon is not congenital but acquired in early childhood; in one case it did not appear until the seventeenth year of life. In the majority of cases the paralyzed eye is highly amblyopic or ametropic. As to the localization and the origin of the phenomenon only theories have been advanced. In a former publication² I have discussed the problem at length and have explained why, in my opinion, the lesion must be localized in the region of the third nu-

cleus. Varying vasomotor influences probably play a part in bringing about automatic alternation of spastic and paralytic phases. The interesting influence of voluntary movement impulses in the course of the phenomenon I have tried to explain as follows: A part of the oculomotor nucleus, which has retained but a slight degree of function, seems to react only if it is abundantly supplied with blood. This is obtained when, by sending an impulse to the oculomotor nucleus, the blood vessels in this region are made to dilate; after a short interval the spastic phase arises. On the other hand, an antagonistic impulse going to the abducens nerve of the paralyzed eye seems to cause an inhibition of the oculomotor excitation by the contraction of its blood vessels; the paralytic phase results. The reasons for my theory are given in detail in the publication just mentioned.

Another interesting group of oculomotor palsies comprises cases of *recurrent third-nerve palsies*, frequently called *ophthalmophlegic migraine*, after Charcot. Their main characteristics are as follows: The first attack starts either in childhood or adolescence with severe headaches confined, as a rule, to one side of the head, frequently followed by vomiting. The headaches last a few days, then cease and are followed by a longer or shorter period of perfect well-being. After one or several years an attack of the same kind is followed by a total paralysis of the third nerve which rapidly develops on the side where the headaches are located, one or several days after the onset of the latter. These abate once the paralysis is complete, which outlasts the headaches for some days or weeks but at last subsides completely. After some recurrence of these attacks the third nerve does not regain its normal function but at first paresis, and finally a total oculomotor paralysis remains while the attacks of headaches may stay

away. The sixth and the fourth nerve participate only exceptionally in the aforementioned attacks. As to their origin, the authors are still at variance. While the symptoms in some cases point to a basal lesion, particularly to neoplasms or inflammatory affections in the region of the superior orbital fissure, the cavernous sinus, and the chiasm, numerous observations lead to the assumption that the attacks of ophthalmoplegic migraine are due to spastic disturbances of the blood vessels, which in the course of time may cause an atrophy of the third nucleus.

Besides the recurrent third-nerve paralyses with the symptoms of migraine, there is a much smaller group of recurrent and alternating palsies of the oculomotor apparatus to be met with in tabes, cerebral syphilis, myasthenia, and multiple sclerosis. At one time one muscle group of one eye is affected, at other times this eye may be normal but the same or other muscles of the second eye paretic, or both eyes may be either partially or totally paralyzed. The disease, the nature of which in the absence of other neurological signs cannot always be cleared up, may drag on for many years.

Among the partial oculomotor pareses the cases in which the paresis is confined either to the exterior or to the interior branches of the third nerve are important with regard to their topic diagnostic value. Although lesions of the trunk of the nerve do not always effect a paresis of all the muscles supplied by the third nerve, in general one is warranted in locating a protracted paresis of either the exterior or interior branches of the nerve in the region of the nuclei and the roots, respectively.

OPHTHALMOPLEGIAS

Paresis of several of the motor nerves of the eyes is called ophthalmoplegia. Acute ophthalmoplegias may be due

either to poisoning (by alcohol, lead, botulism) or to acute infectious diseases (diphtheria, epidemic encephalitis, measles, typhoid fever, and allied diseases). In acute hemorrhagic poli-encephalitis due to alcoholism there is a bilateral ophthalmoplegia confined to all the exterior muscles, while the intraocular muscles remain intact. It develops rapidly and the patients die within one or two days. In botulism the intraocular muscles of both eyes are paralyzed, while some of the external muscles are affected in only about 50 percent of the cases. A characteristic of the postdiphtheretic bilateral paralysis of accommodation is the exemption of the pupils. Pareses of extraocular muscles occur in only 1 percent of diphtheria. All kinds of ocular paralyses are met with in epidemic encephalitis: pareses of single muscles as well as unilateral and bilateral ophthalmoplegias, moreover bilateral paresis of accommodation, anomalies of both the size and the reaction of the pupils, even paralyses of the associated movements pointing to supranuclear lesions. Chronic progressive ophthalmoplegias occur not only in the aforementioned diseases of the cerebro-spinal nervous system (tabes, multiple sclerosis, and so on), but as an isolated disease. In many cases a hereditary disposition has been ascertained. During childhood or adolescence the *single extraocular muscles of the two eyes* become paralyzed very gradually in irregular succession. Sometimes in a later stage the intraocular muscles are also involved (fig. 47A to C). The photographs show one of these cases. The boy's eyes were normal until he was six years old. Then a bilateral ptosis developed gradually. He has never noticed diplopia. I saw him when he was 14 and was able to observe the further development until he was 22 years old. The intraocular muscles of both eyes have always remained intact. His head is habitually

Fig. 47 (Bielschowsky). Chronic progressive ophthalmoplegia. Habitual position of the head (A) compensating for the total paralysis of the elevator muscles and maximal secondary contraction of the depressors (B). C shows bilateral ptosis while the head is erect; maximal convergence occurs when the patient receives an impulse for elevation.

tilted backwards, partly because of a total paralysis of the elevators and an enormous secondary contraction of the depressor muscles. When he is asked to look upward there is not the slightest vertical but a maximal convergent movement of the eyes. In striking contrast to the perfectly normal convergence is the complete bilateral deficiency of the adduction movement in parallel lateroversions, a behavior pointing to a supranuclear origin of that deficiency, since the nuclei and nerves supplying the internal recti muscles react normally to the convergence impulse.

This observation leads to a discussion of *internuclear and supranuclear ophthalmoplegias*. As was said before, the internal rectus is the only ocular muscle possessing two functions at the command of the will, one obeying the impulse to a parallel movement of the eyes, the other governed by the convergence impulse. Both functions, as well as only one, may be destroyed, according to where the lesion has taken place. Loss of the convergence function alone is frequent, owing to either functional or organic disturbances. It will be discussed later on. Loss of adduction in parallel lateroversion while convergence is intact is sel-

dom observed. In the majority of these cases there is an associated paralysis of the lateral movement; that is, the external rectus of one eye and the internal rectus of the other eye are paralyzed. Such cases are to be discussed later. The loss of adduction only in conjugate parallel movements while adduction is normal or less impaired in convergence is very interesting and important on account of its value in topical diagnosis. Such a condition can be caused only by a lesion of the posterior longitudinal bundle between the sixth and the third nucleus (*ophthalmoplegia internuclearis anterior*). This lesion, taking place close to the third nucleus, may cause loss of the adversion faculty of either eye in parallel movements, whereas convergence remains intact. The photographs (fig. 48A to C) show a patient with internuclear paralysis of both internal recti, due to a lesion of the posterior longitudinal bundle. The patient had noticed diplopia three weeks before she came to the clinic. Since the function of the internal recti was fully restored after five weeks, the assumption that there had been a slight hemorrhage within the posterior longitudinal bundles seems warranted.

Besides the internal recti there is only

Fig. 48 (Bielschowsky). Ophthalmoplegia internuclearis anterior. Bilateral loss of adduction in lateroversion (A and B); normal adduction in convergence (C).

one pair of muscles, the unilateral paralysis of which can be attributed positively to a supranuclear lesion. Figure 49A to C shows photographs of a patient with apparently total paralysis of the right elevator muscles (A). The right eye was turned far down, while the left looked straight ahead (B). The maximum impulse to look up raised the right visual line only to the horizontal position (B). Vestibular stimulation of the elevator muscles was just as ineffective. But if the patient was asked to close the eyes and the right lids were pulled open, the right eye could be seen to move up perfectly (C). The integrity of the right

elevator muscles in Bell's phenomenon proves that the nuclei of the nerves supplying the right elevator muscles are intact; only their connections with the cortical centers are destroyed. The lesion must be localized close to the nuclei, below the point where the pathway descending from the cortical centers for the elevation of the eyes bifurcates into the branches which go to both the third nuclei. In a later stage of the disease the paralyzed right elevator muscles responded also to vestibular innervation. But the reaction to the voluntary impulse was never restored.

Another patient had an intracranial

Fig. 49 (Bielschowsky). Supranuclear paralysis of the right elevator muscles: right eye deviates downward while the left eye is in the primary position (A). The maximum impulse to look up brings the right visual line only to the horizontal position (B). Normal reaction of the apparently paralyzed right elevator muscles when the patient is asked to close her eyes (C).

tumor with a metastasis in the neck. X rays showed complete destruction of the greater wings of both the sphenoids and of the sella, pointing to a basal lesion. The diagnosis was supported by an almost complete bilateral ophthalmoplegia and bilateral optic atrophy. The only ocular movement that could be performed was depression. The right eye did not respond at all to the elevation impulse, while maximum effort brought the left visual line just a few degrees above the horizontal plane. In view of the apparently unequivocal basal localization of the lesion, the maximum elevation of the left eye that took place in Bell's phe-

nomenon was all the more surprising. It proved that while the right elevators in the last-mentioned test were functioning no more than in all the other tests, the nuclei as well as the nerves supplying the left elevators were intact but cut off from all their supranuclear connections, except the pathway used in Bell's phenomenon, by a part of the tumor extending up to the corpora quadrigemina.

These observations, the only ones which have been published, are important for topical diagnosis. One should never forget to examine whether and how apparently totally paralyzed elevator muscles react in Bell's phenomenon.

AN INNOCUOUS CLINICAL ENTITY SIMULATING TABES DORSALIS

PUPILLOTONIA WITH ABSENT TENDON REFLEXES (ADIE'S SYNDROME)

JOHN H. BAILEY, M.D., AND EDWARD SASKIN, M.D.
Brooklyn, New York

In August, 1937, H. F., aged 25 years, possessing a sound mind in a sound body, consulted me because he had repeatedly been refused life insurance on the ground that he exhibited metaluetic manifestations. He had large pupils that were immobile to light but reacted to accommodation-convergence; in addition, his ankle and knee jerks were absent. His sister, aged 24 years, in sound health and well poised, presented a similar clinical picture.

In 1902, Strasburger¹ described a hitherto-unknown pupillary anomaly characterized by (1) unilaterality, (2) mydriasis, (3) fixity to light, directly and consensually, and (4) a unique contraction upon convergence. Later in the same year, Saenger² reported several cases that conformed with Strasburger's observations. Saenger believed that the site of the disturbance was in the iridic musculature *per se*, and that the disorder was of the same nature as obtains in myotonia congenita (Thomsen's disease), hence his designation, "myotonic pupillary reaction." The outstanding feature in all these cases was the unusual behavior of the pupil to the stimulus of convergence. Since myotonia congenita and this pupillary abnormality are now regarded as unrelated entities, the term *pupillotonia* is preferred by most writers on the subject; for the striking characteristic of the picture is the sustained contraction or the continued tonicity of the pupil after the stimulus is removed. In 1899, Piltz³ had already noticed that in certain instances, the Westphal-Piltz reflex revealed a pupillary response that is quite similar to that of pupillotonia.

Pupillotonia presents the following features: The phenomena are almost always limited to one side. The affected pupil is wider than its fellow. It is unmistakably dilated, is frequently eccentric and moderately irregular. It is said to be uninfluenced by fatigue, excitement, or the state of health.⁴ When tested in the routine fashion, the pupil does not react to light directly or consensually. When focusing upon a near object, there is no immediate contraction of the pupil; this may give the impression that the pupil is inactive to the accommodation-convergence stimulus. However, as the patient persists in the near gaze, the pupil, after a short interval, starts to contract leisurely but at a progressively diminishing rate until miosis obtains, which may reach an extreme degree. When the patient now looks into the distance, the pupil does not relax immediately; in fact, it may continue to contract still more before commencing to dilate to attain its original diameter, the dilatation being more tardy than the contraction and covering a longer period of time. The delay in both phases of the pupillary response may be considerable. Holmes⁵ reports a case in which 5 minutes elapsed before the pupil contracted upon convergence, and even more time was consumed in its relaxation. Although the photomotor reflex appears to be abolished, that is actually not so, for it can be evoked by a special procedure. If the patient is kept in a dark room about an hour, it will be noticed that the involved pupil is now a little larger than it was previously, and that the fellow pupil approximates it in size. If the eyes are

then suddenly exposed to bright diffuse light, for example, a room flooded with sunlight, the affected pupil, after a short delay, will sluggishly contract to its original size, or may become somewhat smaller; in the latter event, there may be a perceptible interval before the pupil resumes its usual diameter. Not infrequently, corresponding to the persistent contraction of the pupil upon convergence, there is an accompanying spasm of the ciliary muscle, causing an annoying dysfunction of accommodation: the patient sees a near object distinctly, but, upon looking in the distance, his vision is blurred for several seconds or more until the ciliary muscle relaxes. Although the amount of accommodation is increased—that is, the patient can accommodate to a point nearer to his eyes—the range, nevertheless, is greatly diminished or may be practically nil. In one instance, the patient saw the appropriate near type distinctly only at a distance of 15 cm., no nearer and no farther. This disturbance continued about 6 seconds, and it took 50 seconds more before the accommodation resumed its usual flexibility. Reitsch⁶ quotes a case of pupillotonia in which the ciliary spasm lasted an hour, causing a severe headache which was relieved by homatropine. The following data, taken from an article by Behr,⁷ depict a typical example of pupillotonia.

Right pupil (abnormal)

Diameter of pupil, patient facing window, 5.5 mm.
Diameter of pupil, patient's back to window, 6 mm.
Diameter of pupil, three-fourths hr. sojourn dark room, 7 mm.
Diameter of pupil to convergence, 2.5 mm.

(a contraction of 3.5 mm.)

When patient converged to 30 cm., 6 seconds elapsed before pupil responded, remained contracted for 10 seconds after removal of stimulus, and then sluggishly dilated, attaining its normal width in 50 seconds.

Upon focusing at a distance of 30 cm., after an interval of 6 seconds, spasm of accommodation occurred, bringing both the far and near points to a fixed distance of 15 cm., thus extinguishing completely the range of accommodation. This lasted 10 seconds, when the spasm gradually relaxed, and normalcy was reached in 50 seconds.

Westphal-Piltz reflex, exaggerated.

Pupillotonia may digress from the norm. The following deviations have been noted: (1) The pupil does not maintain a uniform dilatation; it may vary in size even in the course of the examination, although only to a moderate degree. (2) The light reflex cannot be elicited in spite of the most painstaking effort. (3) The reaction to convergence offers nothing unusual except for a slow dilatation upon removal of the stimulus; or the reaction may be typical on one occasion and perfectly normal at other times. (4) The pupil is absolutely immobile to light and to convergence. (5) The previously tonic pupil may become subsequently totally fixed, having ceased to react to light and to convergence; and, conversely, a fixed pupil may exhibit later on characteristic tonic phenomena. (6) Bilaterality, though very rare, yet strangely present in the two cases reported herein. (7) Both pupils show one or more of the variations enumerated above, or one pupil is typically tonic and the other manifests these variations.

Cases of iridoplegia and ophthalmoplegia interna totalis (so-called fixed pupils), whose origin is unknown, are regarded by Adie⁸ as aberrant forms of pupillotonia.

In pupillotonia, the pupil contracts promptly and vigorously to pilocarpine, eserine, and cholin preparations. Cocaine

and atropine produce the usual dilatation; and if adrenalin is now added, further dilatation (maximal mydriasis) takes place.

An important associated sign is loss of the deep reflexes. As a rule, the reflexes are absent on both sides; exceptions, however, are not uncommon. Some of these reflexes may be missing on one side, and different ones missing on the opposite side. The reflexes most frequently affected are the ankle jerks, then the knee jerks and arm jerks.

Adie⁹ divides pupillotonia into (1) complete forms and (2) incomplete forms. The latter are subdivided into (a) tonic pupils alone, (b) atypical phases of tonic pupil alone, (c) atypical phases of tonic pupil with absence of the deep reflexes, and (d) absence of deep reflexes alone.

Pupillotonia, when accompanied by the loss of deep reflexes, suggests to the attending physician tabes dorsalis, and such cases have been subjected to prolonged antiluetic treatment, to the mental and financial distress of the unfortunate patient. The tonic pupil is naturally mistaken for the Argyll Robertson pupil. A careful analysis will readily establish the differential diagnosis. In the first place, the Argyll Robertson pupil is only exceptionally unilateral, in which case the affected pupil is the smaller one; while in pupillotonia, the affected pupil is always larger than its fellow. As a rule, in pupillotonia the pupil is less irregular than is the Argyll Robertson pupil. The Argyll Robertson pupil is refractory to the light stimulus under all circumstances, and it will not dilate upon a long sojourn in the dark. It responds promptly to accommodation-convergence, and dilates as promptly when the stimulus is removed. Atropine does not produce a maximal dilatation, and cocaine is altogether ineffectual; in pupillotonia these drugs exhibit their full action. When the photomotor reaction is

absent in pupillotonia, subcutaneous injection of strychnia will provoke a definite though feeble response, or will augment it, if it is weak; this does not occur with the Argyll Robertson pupil. In a miotic Argyll Robertson pupil, the psychosensory dilator response is apt to be subnormal. Two opposing factors normally participate in this reflex, a sympathetic and a parasympathetic. A sympathetic stimulus is sent, via the cilio-spinal center and the cervical sympathetic, to the dilator iridis, causing this muscle to contract; and a parasympathetic stimulus is transmitted simultaneously, via the third nerve, to the sphincter iridis to cause it to relax, each stimulus producing, on its own account, a widening of the pupil. In the Argyll Robertson pupil, the sympathetic element is likely to be impaired, owing to spinal-cord involvement; this would reduce the psycho-sensory effect. In pupillotonia, the psycho-sensory reflex is normal. The Westphal-Piltz phenomenon shows nothing unusual in the presence of the Argyll Robertson pupil, but in pupillotonia the reaction may assume a tonic character. In pupillotonia, the pupil may vary in size and performance during the examination; the Argyll Robertson pupil does not behave in such manner. Cases of pupillotonia that have been observed for years, have at no time displayed any evidence of syphilitic infection; there were no familial nor degenerative stigmata, the blood and spinal fluid were repeatedly negative, visual fields and eye grounds normal, there was no palsy of the extrinsic ocular muscles, and the general skeletal musculature was unaffected. Accordingly, the writer agrees with Bramwell¹⁰ *et al.*, that pupillotonia is a clinical entity of an innocent and innocuous nature. Syphilis of the nervous system that does not manifest, at any time, any signs or symptoms except pupillotonia and absent tendon reflexes, does not exist. Moore¹¹ reported under the

caption "Non-luetic Argyll Robertson pupil" a series of cases that doubtless belongs to the category of pupillotonia. In passing, one might mention the neurotonic pupillary reaction, a photomotor phenomenon analogous to the convergence reaction in pupillotonia. The cause of the neurotonic pupil and its explanation are obscure.

Instances of atypical pupillotonia have been diagnosed as the ocular sequelae of diphtheria. In diphtheria, there is usually the history of a specific infection, the ophthalmoplegia interna is commonly bilateral, and frequently limited to paralysis of the ciliary muscle, the symptoms appear a few weeks after the acute course has subsided, and, as a rule, there is a comparatively early complete recovery. The peculiar response of the pupil to convergence is absent. In addition, the pupil contracts to the near reflex to a less extent than normally, assuming that the innervation of the sphincter iridis is intact. In this connection, it may not be amiss to call attention to the physiology of the near reflex. When a person focuses upon a near object, there is a distinct contraction of the pupil caused by the acts of accommodation and convergence. In paralysis of accommodation alone, the pupil will still contract, although to a less extent. The same holds true in paralysis of convergence alone, as may occur in encephalitis lethargica. In paralysis of both accommodation and convergence, the near reflex is completely abolished. Thus the amount of contraction of the pupil to the near reflex is the sum of the contraction due to the accommodation plus that due to the convergence.

A case of diabetes may unexpectedly reveal absent knee jerks and pupils that do not react to light but do react to the near reflex. Such a case may be accompanied by some of the features of atypical pupillotonia.

Since pupillotonia appears in the standard textbooks under the title "The myotonic pupillary reaction," it seems pertinent to state briefly wherein it differs from those myopathies that are characterized by myotonic phenomena, particularly myotonia congenita or Thomsen's disease. In the various myotonic disorders, only the striped or voluntary muscles are involved, while in pupillotonia, the disturbed function affects smooth muscle. A patient afflicted with myotonia congenita has no difficulty in initiating any movement; there is no delay or latent period, contrary to what occurs in pupillotonia. It is true that in the myotonias, once the muscles contract, they remain in a spastic condition for some time; for example, when the eyes are closed, they can be opened only slowly and after the expenditure of much effort. Frequent repetition of the act causes a temporary recession of the disturbance. In pupillotonia repetition does not ameliorate the dysfunction. The pharmacologic test is of value. Quinine produces an immediate and spectacular, though short-lived, subsidence of the symptoms in myotonia congenita, but is inert in pupillotonia. In the myotonias, the deep reflexes are preserved and pupillary changes are uncommon. Conversely, in pupillotonia there is no involvement of the skeletal muscles. In the myotonias, the muscles themselves or their myo-neural junction is at fault; in pupillotonia, the anomaly is based upon a distant factor. In myotonia atrophica, presenile cataract is a frequent occurrence and may direct attention to the diagnosis of the myopathy. A pronounced sleepy look, owing to a drooping of the upper lid, is characteristic.

Adie's statement that pupillotonia is a disease *sui generis* is disputed by those who contend that cases of pupillotonia should be divided into two distinct groups: (1) pupillotonia appearing as the sole clinical manifestation in a healthy

individual, (2) pupillotonia as part of a general morbid state. It is to the first group, that the eponym "Adie's syndrome" may appropriately be applied, although much credit accrues to Behr for his thorough study of the subject, whose brilliant contributions were published 10 years before those of Adie. Pupillotonia has been reported in encephalitis lethargica, migraine, diphtheria, chronic alcoholism, contusion of the eyeball, cranial injuries, and herpes zoster ophthalmicus. Patients presenting Adie's syndrome in the above restricted sense, are mostly young females in good health with loss of the deep reflexes; while in the other group, there is no sex preference, areflexia is not a part of the clinical picture, and there is a recognizable extraocular disease in addition to the pupillary anomaly.

Regarding the etiology, pathology, and pathogenesis of pupillotonia, we have no definite knowledge; our views, at best, are merely speculative. Some believe that a neurotropic virus is the offending agent, others hold the view that a neurosis or a psychosis is at the bottom of the trouble, still others implicate the endocrines.

As to the site of the pathological process, again opinions differ. Saenger thought the muscles of the iris were primarily involved—that is, that the lesion was of a myopathic nature—a view that has few adherents. Many¹² are inclined to ascribe the disorder to a disturbance in certain parts of the third-nerve-nucleus district or cerebrad thereto. They hold that the vegetative nervous system sending impulses to the respective muscles via the parasympathetic is responsible for the disturbance. In about one third of the cases¹³ there is additional evidence that the vegetative nervous system is implicated: vasomotor instability, and anomalies of perspiration and of skin temperature. Loss of deep reflexes has been observed in catalepsy, narcolepsy, family

periodic paralysis, myasthenia gravis, the myopathies, Graves's disease, and other affections, conditions in which there is apparently no organic change in the reflex apparatus. Respecting the *modus operandi* of pupillotonia, Behr theorizes as follows: In the domain of the nucleus of the third nerve are parasympathetic cell groups that subserve accommodation and the photomotor and near reflexes. These cells have become or are inherently sluggish in action, and when stimulated there is no immediate response, the energy of the stimulus being stored up or accumulated in the cells. This energy is then slowly discharged, even after the stimulus is removed, thus accounting for the peculiar behavior of the pupil. There is a perversion of function, not due to any organic lesion, but rather dependent upon an abnormal physico-chemical change in nerve tissue.

The view that pupillotonia is a result of emotional instability, that it is of psychotic origin, or a neurosis, will not explain that the anomaly is unilateral, that it occurs in persons in sound physical and mental health, and that it persists, as a rule, unaltered over years of observation.

The following is a summary of the cases of two patients who have been under my care since August, 1937.

H. F., a white male, in good health, had a negative history. He had high myopia; his corrected vision, O.U. was 20/20. Ocular excursions were normal, as were also the visual fields and eye grounds. The right pupil was irregularly oval, the left pupil pear-shaped. In good daylight, the right pupil measured 3 mm. in diameter, the left 4 mm. Neither pupil reacted to light directly or consensually when examined in the usual way. However, after a sojourn of one-half hour in the dark room, the right pupil was 5 mm. wide, the left 4½ mm. Upon focus at 8 cm., after a latent period of 3 seconds, the right pupil contracted slowly to 2 mm.,

and then when the gaze was directed to distance, dilated leisurely, consuming 60 seconds before attaining its former size. The left pupil required 3 seconds to elapse before it responded to accommodation-convergence, contracted to $2\frac{1}{2}$ mm., and remained thus contracted for 6 seconds after the removal of the stimulus, reaching full dilatation in 28 seconds. There was no associated accommodative spasm. The Westphal-Piltz and psychosensory reflexes were normal. In the course of the examination, the pupils would vary appreciably in size without any apparent reason. The tendon reflexes were absent.

I. F., a sister of H. F., 24 years old, unmarried, had a negative history. She also had a high myopia, and corrected vision was 20/20. Both pupils were dilated, the right to a greater degree. They were moderately irregular and eccentric; there were no synechiae. Neither pupil reacted to light directly or consensually, even after a prolonged stay in the dark. Typical tonic convergence reaction proved the pupils slow to respond; they remained contracted after removal of the stimulus, and then slowly dilated. Ankle and knee jerks were absent.

SYPHILITIC OPTICOGHIASMATIC ARACHNOIDITIS*

DERRICK VAIL, M.D.

Cincinnati

Basilar meningitis due to syphilis has been recognized for many years. Oppenheim, in 1911, stated that—"The chief form of brain syphilis is basal gummatous meningitis. It usually arises from the sub-arachnoid tissue in the region of the chiasma, from the space between the cerebral peduncles, and thence it extends more or less widely in a diffuse, although irregular, manner over the base of the brain. At some points, and often over a wide extent, it forms a firm, connective-tissue induration, which adheres firmly to the basal parts of the brain. It penetrates into all the bifurcations and depressions, and spreads like a veil over the origin of the cranial nerves. . . . The basal meningitic process may also be limited to a small area, *e.g.*, to the neighborhood of the oculomotor nerve, the chiasma, etc." The chiasm and other cranial nerves are bathed in cerebrospinal fluid as they traverse the various cisterns of the brain, the most important, from our viewpoint, being the cisterna chiasmatica and the cisterna interpeduncularis. The access thus provided for infection to reach the cranial nerves explains the early incidence of cranial-nerve palsies in the course of basilar meningitis. In addition to the nerves, innumerable blood vessels range through the cistern and thus carry the infective agent into the cerebrospinal fluid at these points. Gravity and cisternal stasis perhaps play a role in localizing the process at various areas. This would explain the predilection of the infective agent for the base of the brain and posterior fossa, the latter particularly from middle-ear disease.

It is well known that syphilis has a tendency to involve the crevices and folds of the central nervous system (Friedman, Brock, and Denker). The changes consist of an inflammatory exudation into the meninges, in which spirochetes are found, but especially in focal accumulations of cells in the meninges, particularly in the walls of blood vessels and in the adjacent substance of the brain itself (MacCallum).

Igersheimer (1918) terms the region of the optic chiasm the "Lieblingsitz," or "favorite seat," of basal syphilis, and discusses chiasmatic syphilis at great length. When other cranial nerves are involved, it is not difficult to recognize syphilitic basilar meningitis, but when the optic nerves and chiasm alone are implicated, the arachnoid nature of the syndrome of atrophy of the optic nerve and visual-field defects is frequently unsuspected or is mistaken for parenchymatous syphilis, that is, *tabes dorsalis*, as Hausman has pointed out. When all other chiasmal lesions—for example, (1) intrasellar lesions, (2) suprasellar lesions, and (3) parasellar lesions, including aneurysm of the circle of Willis, tumor of the optic chiasm or optic nerve, traumatic lesion of the optic chiasm, oxycephaly, and heredodegeneration—have been excluded, the underlying cause is arachnoiditis. Just as the nonsyphilitic cases of chiasmal arachnoiditis have shown improvement or recovery by surgical intervention, so arachnoiditis due to syphilis has yielded to surgery, with, in a few cases, improvement of vision. Modern neuro-surgery has revealed many lesions the nature of which has hitherto been entirely unsuspected. Among these is opticochiasmatic arachnoiditis. The nonsyphilitic form has been extensively studied, notably by Craig and

* Read at the Seventy-fourth Annual Meeting of the American Ophthalmological Society, at San Francisco, California, June 9-11, 1938.

Lillie, Heuer and Vail, Davidson, and especially by French investigators. A recent monograph on the subject by Bollack, David, and Puech analyzes at great length 129 surgically verified cases, and forms an exceedingly valuable contribution to the subject. Thirteen, or 10 per cent, of these collected cases had positive blood and/or spinal-fluid Wassermann tests. Adhesions due to arachnoiditis involving the chiasm were found at operation, in all cases, and were freed as thoroughly as possible. It is pertinent here to analyze the postoperative visual result in these cases. Six showed no improvement; three became somewhat worse as time went on. All these cases, so far as preoperative vision was concerned, were practically hopeless. The postoperative result was considered good in two cases, the vision improving in one eye from zero to 1/50 in one case and from 5/7 to 5/5 in the other. Two cases showed slight visual improvement (from shadows to 1/100, and from 1/35 to 1/25). One case remained unchanged (5/50 both eyes). In one patient the postoperative visual result was not stated, and one patient died following operation. These results are not, to be sure, very encouraging, but the unfavorable outcome, as has been pointed out, occurred in patients in whom the optic nerves were very much atrophied, and in whom prognosis for recovery of useful vision could be regarded as positively hopeless.

Hausman has recently reported five cases of syphilitic arachnoiditis of the optic chiasm. One patient (case 1), a Negress, aged 26 years, had suffered severe intermittent headaches for four years, bilateral anosmia for three years, and progressive loss of vision for two years. There was almost complete blindness in the left eye, temporal hemianopia in the right eye, and bilateral primary atrophy of the optic nerve. The Wasser-

mann reaction of the blood was 4+, and of the cerebrospinal fluid was negative. X-ray examination showed a shallow sella, with poorly outlined clinoid processes. Craniotomy with liberation of chiasmal adhesions was performed. Prompt improvement in the visual fields resulted, and one month after operation the vision had steadily improved in both eyes. Three patients were not operated upon, and intensive antisyphilitic treatment was of little benefit, only one case showing slight improvement. One patient died a year after coming under observation and treatment. Autopsy revealed a gumma of the right parietal lobe, and perichiasmal syphilitic plastic meningitis. Microscopically there was gummatous meningitis of the optic chiasm.

Bollack, David, and Puech believe that in certain cases the realm of opticochiasmatic arachnoiditis can be extended to include tabes. In other words, a tabetic person can have arachnoiditis. These observers quote Mme. Schiff-Wertheimer as follows: "We have seen that the meningitic lesion is not sufficient to explain the pathologic process that affects the nerve trunk. On the other hand, we have insisted on the frequent beginning of the lesions at the periphery of the nerve and believe that section of the meninges and the resultant drainage can have a favorable influence."

Recent studies by Greenfield and Epstein indicate that they corroborate the findings of Schiff-Wertheimer, Stargardt, Behr, and Igersheimer that chronic meningeal inflammation is the cause of tabetic optic atrophy. It was found that the superficial fibers in the optic nerve were affected first, that the myelin was affected more than the nerve fibers, and that inflammatory changes in the meninges were much more evident in the intracranial than in the intraorbital portion of the optic nerves.

David, Hartmann, and Hebert reported the case of a tabetic male, aged 48 years. In 1936 his vision, especially in the right eye, began to fail rapidly. The field of vision showed marked loss in the lower portion. The vision in the right eye was reduced to 2/10; in the left eye, to 3/10. Blood Wassermann and Kahn tests were strongly positive. Bilateral optic atrophy was present. Antiluetic treatment was administered, but six months later the fields of vision showed still further loss. Craniotomy and exposure of the chi-

asma revealed a widespread leptomeningitis extending over the entire frontal lobe. There were large white sheets of scar tissue on the sylvian fissure. The right optic nerve was concealed by an enormous white-banded sheet of tissue, suggesting a cystic membrane, from beneath which a large amount of fluid exuded. The optic nerves were freed carefully. Two months after the operation the vision in the right eye was 3/10; in the left eye, 5/10. The field of vision had improved.

Fasiani reported a case of tabes in which arachnoidal adhesions around the optic nerves were found and freed. (The details of this case are not available.) On the other hand, Sourdille and David reported a tabetic case in which operation did not disclose any arachnoidal adhesions. The two optic nerves were small, reddish gray, and were the seat of inflammation and atrophy. There was no basilar meningitis, but an enormous amount of fluid escaped from the chiasmal

Fig. 1 (Vail). Exposure of right optic nerve (case 1).

cistern. There was no postoperative improvement of vision, but, strange to say, the patient's ataxia improved remarkably, a fact that the authors cannot explain. The fields of vision were not typical of a chiasmal lesion, showing concentric contraction only.

CASE REPORTS

Case 1. W. F., white, male, aged 58 years, was first examined on March 2, 1938. He complained of poor vision, especially in the right eye, for at least five years, and probably longer. In November, 1930, he had struck the right part of his head, immediately after which he noticed that the vision in the right eye was poor. The left eye was normal at this time. He consulted an optician, who referred him to an ophthalmologist. Glasses were prescribed. At this time the vision in the left eye was normal, but no cause for the poor vision in the right eye was given. In 1933 he was seen by another ophthalmologist, who found primary optic atro-

phy in both eyes and diagnosed the condition as tabes. The pupils were moderately dilated and did not react to light nor consensually. Both discs were pale, but the right especially so. On August 29, 1933, the vision was: R.E., no light perception; L.E., 15/15, and J.6 with a +2.50 D. sph. added, indicating that there was probably a relative central scotoma. Wassermann was 2+; Kahn, 4+. Mer-

ferred severe headaches. At the General Hospital in 1935 he was given malarial treatment. He believed that his vision improved, or at least that it remained stationary for a time. Then it became steadily worse in the left eye until, on March 22, 1938, the vision in the left eye had been decreased to the ability to count fingers at three feet.

Examination: The right pupil was

Fig. 2 (Vail). Fragment of arachnoid membrane removed at operation (case 1).

curial ointment and intravenous salvarsan medication were prescribed.

A year later the blood Wassermann was 4+. The vision in the left eye was reduced to 15/50, and a large central scotoma was found which the ophthalmologist believed was the result of the salvarsan injections. June 21, 1934, inhalations of amyl nitrite were given, the vision being 15/24 after the second inhalation and 15/19 after the third. Hypodermic injections of sulphuric oil and amyl-nitrite inhalations were prescribed during July and August, 1934. The final vision in the left eye was 15/19. The patient was not seen again until February 4, 1935, when the vision in the left eye had been reduced to 15/200. Unfortunately, the ophthalmologist had misplaced his fields of vision in this case. The patient reported that following the medication, particularly after the intravenous injections, he suf-

fered severe headaches. At the General Hospital in 1935 he was given malarial treatment. He believed that his vision improved, or at least that it remained stationary for a time. Then it became steadily worse in the left eye until, on March 22, 1938, the vision in the left eye had been decreased to the ability to count fingers at three feet.

Examination: The right pupil was semidilated, did not react to light, but did react to accommodation. Ophthalmoscopic examination revealed the presence of a mixed type of optic atrophy: The outline of the nerve head was sharp, the blood vessels were markedly reduced, the lamina cribrosa was visible, and the color of the nerve head was a pale whitish green. In view of the patient's history, and what can be considered as adequate antiluetic treatment, a diagnosis of opticochiasmatic arachnoiditis was made, and the patient was referred to Dr. Howard McIntyre, a neurologist, who confirmed the diagnosis and advised craniotomy. On April 4th this was performed by Drs. Nolan Carter and Joseph Evans at the Good Samaritan Hospital. A right frontal lobe exposure was made, and an excellent view of the chiasm and the optic nerves was obtained. The cortex of the brain was covered with a thin, plastic membrane, which was

patchy and irregular.

Old exudate was deposited along the great vessels. The exposure of the chiasm revealed (fig. 1) a thin membrane, not unlike filter paper, covering the optic chiasm and the blood vessels. A piece of this membrane was removed for biopsy. An examination of the pathologic specimen revealed the presence of a thickened arachnoid with epithelioid cells and secondary fibrosis (fig. 2). The adhesions were much thicker and more numerous on the left optic nerve. In fact, on the

Fig. 3 (Vail). Exposure of left optic nerve (case 1).

first exposure of the left optic nerve it was thought that the nerve was shrunk to a thin thread, but careful dissection disclosed that this appearance was due to the membrane infringing on three fourths of the width of the nerve, to such an extent that the rest of the nerve was not visible. This membrane was resected and pushed back out of the way, revealing a normal-sized optic nerve (fig. 3) that was a little paler than usual. There was some flattening of the optic

nerves as they entered the optic foramen. A large amount of clear fluid was evacuated from the cisterna chiasmatica.

The first few days after the operation were stormy, and because of secondary hemorrhage, the bone flap was elevated and a blood clot removed. After that the patient showed a steady improvement. The examination of the optic-nerve heads two days after operation showed no change. Apparently the vision had not changed either. On May 18, 1938, the

right eye had no light perception, but with the left eye the patient could count fingers at 10 feet. There was good light projection in all parts of the field, especially in the temporal field, but doubtful in the center. The patient's wife stated that she had noticed a decided improvement in his ability to go about the house, although he did not think his vision had improved much, if any. The field of vision was as seen in figure 4.

Case 2. F. B., white, male,

Fig. 4 (Vail). Field of vision (W. F., case 1).

Fig. 5 (Vail). Field of vision (F. B., case 2).

aged 35 years, a salesman, was first examined on September 20, 1937, when he gave a history that the vision in the left eye had become poor one month previously. Everything seemed to be blurred, and vision gradually grew worse, so that he was no longer able to read with the left eye. There was no history of any inflammation or injury. His general health had always been considered good. He denied venereal infection.

Examination: Vision in the right eye was 20/15—1, and J.1; the eyeball was free of congestion, the pupil was of normal size and reacted somewhat sluggishly to light. The vitreous was clear; the optic-nerve head was sharply defined. The latter was very pale, with a visible lamina cribrosa and deep physiologic cupping.

The vessels were somewhat constricted. With the left eye the patient counted fingers at six feet. The left pupil did not respond to light or accommodation. The disc outline was sharply defined, with deep physiologic cupping. The nerve head was very pale, and the vessels were markedly reduced in size. The biomicroscopic examination was negative. The fields of vision were as seen in figure 5. The patient was referred to Dr. Howard McIntyre

for a neurologic examination. He found absent knee jerks, diminished abdominal reflexes, and slight ataxia, especially in the left leg. The Romberg sign was slightly positive. Pain sense was diminished from the first lumbar segment downward in the left leg; the vibratory sense was diminished in both legs. The spinal-fluid pressure was normal, and showed a positive Wassermann, 90 lymphocytes per cubic millimeter, luetic type of gold curve, and an excess of globulin. The blood Wassermann was likewise positive. A diagnosis of meningovascular lues was made, and the patient was placed on antiluetic treatment. On December 1, 1937, he returned. The vision in the right eye was reduced to 20/50—, and with the left he could count fingers at six feet.

There was no change in the appearance of the disc. At a subsequent examination on December 21, 1937, vision was: R.E., 20/50; L.E., ability to count fingers at six feet. On February 7, 1938, vision in the right eye was reduced to 20/200, and in the left it was as before. Both discs were very pale, with a visible lamina cribrosa and marked vascular constriction, about equal in each eye. The vision with both eyes open was 20/200, and was a little better in

Fig. 6 (Vail). Field of vision (F. B., case 2).

dim illumination. The fields of vision are depicted in figure 6. On May 4, 1938, vision was: R.E., 20/200; L.E., ability to count fingers at $2\frac{1}{2}$ feet on the temporal side. The nerve heads exhibited no change. A tentative diagnosis of chiasmal arachnoiditis was made, and operation was advised, but the patient refused to consider surgery. During these months active antiluetic treatment had been carried out, including 10 chills with malaria. The fields of vision were as seen in figure 7.

Case 3. M.E., white, male, aged 61 years, was referred by Dr. N. A. Martin, Gallipolis, Ohio, in consultation. Dr. Martin reported that when he first saw the patient in October, 1937, the visual acuity in the left eye was reduced to the ability to detect hand movements at two feet, and the corrected vision in the right eye was 20/30. Both discs were pale, and there was marked constriction of the retinal vessels. The blood Wassermann was 4+. He was placed on antisypilitic treatment, but in spite of this the visual loss was progressive. He was examined by me on February 14, 1938. He stated that two or three years previously the vision in his left eye had suddenly grown dim. At that time he was told by an ophthalmologist that he had had a hemorrhage in the eye, and that nothing could be done for him. Six months ago the vision in the right eye had begun to fail.

Examination: Vision in the right eye, uncorrected, was less than 20/200; corrected, 20/30+ and J.2. The pupil was slightly enlarged, but reacted sluggishly to light. The lens was clear, but the vitreous showed fine, dustlike opacities. The optic-nerve outline was sharply defined, with normal

physiologic cupping and a visible lamina cribrosa. The entire optic nerve was pale, particularly on the temporal side. The vessels were markedly reduced in caliber and irregular. There were signs of vascular hypertension. An old, minute spot of focal choroiditis was present near the disc margin, below the temporal side. The palpebral fissure was more widely open than normal. In the left eye vision was reduced to light perception only—no projection. The pupil was dilated and fixed. The outline of the nerve head was somewhat pale and blurred. There was marked pallor of the nerve head, the lamina cribrosa was not visible, and the vessels were much reduced in size. The macular area appeared to be somewhat edematous, and was stippled with pigment as if it had been

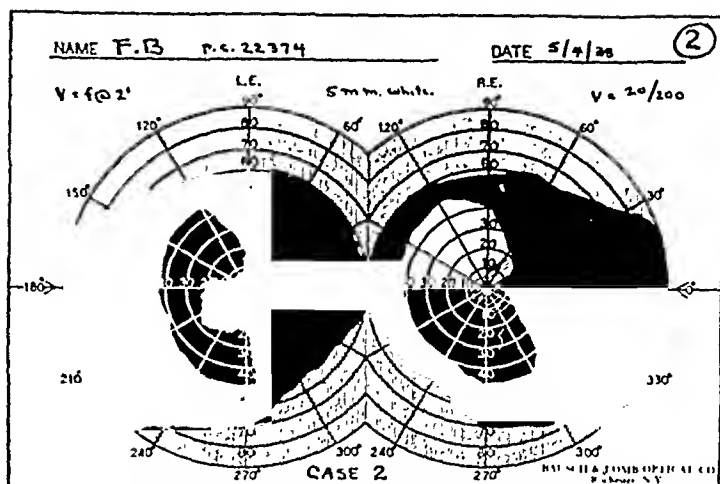

Fig. 7 (Vail). Field of vision (F. B., case 2).

Fig. 8 (Vail). Field of vision (M. E., case 3).

Fig. 9 (Vail). Field of vision (L. B., case 4).

alyzed, and the left eyelid drooped partially. She developed headaches of a pounding, continuous character, deep in the left temporal region and above the eye. The headaches continued unchanged until September, when they subsided to a dull ache which gradually disappeared. One year later the headaches recurred, and the left eyelid again drooped. Her speech became mumbling. She said that her eyesight had always been poor, and that she had

the seat of an old macular hemorrhage. There was a new blood-vessel formation, and proliferative retinitis three disc-diameters from the edge of the disc along the superior temporal artery was present. The fields of vision are shown in figure 8. Malarial treatment was advised, with the understanding that if the progress of failing vision in the right eye were not checked, an exploratory operation of the chiasmatic area should be undertaken.

In a letter of April 8, 1938, Dr. Martin reported as follows: "His eye condition at the present time shows some increase of the visual field—the red target is well visualized over twice the area it was previously noted. He stood 12 severe chills with marked temperature reaction very well, and his general condition improved." Because of the improvement in his field of vision, the patient reasoned that operative interference should be undertaken only as a last resort after every other means had failed to help him.

Case 4. General Hospital No. 79927. L. B., colored, female, aged 27 years, was throughout 1934 a patient in the Branch Hospital, with a diagnosis of far-advanced pulmonary tuberculosis with cavitation in the right apex. She was discharged in 1935. In July, 1936, she complained of numbness of the face. Two days later her right side became par-

changed glasses frequently.

The physical examination was negative, except for evidence of an arrested tuberculosis at the right apex. The neurologic examination, made on September 30, 1937, showed complete left third-nerve paralysis and marked lower right side seventh-nerve weakness. The tendon reflexes on both sides were active. Blood examination: Kahn, 3+. Spinal fluid examination: Wassermann, 3+, positive gold curve, protein, 165 mg. per 100 c.c. Blood pressure, 100/72.

The ocular examination on April 13, 1938, showed vision in the right eye to be 6/200. The pupil was dilated, but reacted. The disc was pale, with sharp outline, visible lamina cribrosa, and the vessels were reduced in size. The left eye diverged about five degrees. The pupil was dilated, and did not respond to light. The disc was atrophic, with sharp outline, visible lamina cribrosa, and the vessels were reduced in caliber. Vision in this eye was reduced to no light perception. The vision in the right eye, with +3.75 D. sph. = + 2.00 D. cyl. ax. 175°, was 20/70. The vision in the left eye could not be improved. The field of vision showed a sharply evident temporal defect (fig. 9). A diagnosis of syphilitic arachnoiditis and syphilitic thrombosis of the cerebral vessels with a bilateral mixed

type of optic atrophy was made. The patient had had inadequate antisyphilitic treatment, and it was considered wiser to try conservative treatment before undertaking surgery.

Case 5. General Hospital No. 43842. W. P., white, male, aged 64 years, had in February, 1937, noticed blurred vision of the right eye. He exhibited no other symptoms except a chronic cough.

Past history: In 1909 he had had an apoplectic stroke affecting the left side and causing diplopia. The paralysis subsided in 24 hours, but weakness persisted for six months. There was a history of chancre at the age of 19 or 20. He had received only four therapeutic injections. On March 11, 1937, the blood Wassermann was negative; the Kahn test was positive. The vision in the right eye was 5/200 unimproved, and the pupil did not react to light. The disc was very pale, with indistinct nasal border, and the vessels were markedly reduced in size; the color of the nerve head was white, and the lamina cribrosa was visible. The vision in the left eye, which had been 20/20 in 1937, was now reduced to 20/100; the pupil reacted sluggishly; the disc was slightly pale, with sharply defined border; the blood vessels were reduced in size, and the lamina cribrosa was visible. Blood pressure, 140/90. The field of vision is shown in figure 10.

Case 6. General Hospital No. 91810. A. H., colored, male, aged 42 years, first noticed dimness of vision in the right eye in February, 1938. One month later the vision in the left eye began to fail. He complained that at this time he could not see anything with the right eye. A history of chancre in 1929, gonorrhea in 1919, and again later, was given. He drank about one-half pint of "moonshine" daily from 1922 to 1929.

Fig. 10 (Vail). Field of vision (W. P., case 5).

Physical examination: Blood pressure, 220/140. The motor and sensory systems were intact. The Kahn test and blood Wassermann were strongly positive. Spinal-fluid examination revealed a positive Wassermann and a positive gold curve. The vision in the right eye on March 30, 1938, was light perception only; in the left eye, it was 20/30. On May 16, 1938, the vision in the right eye showed no light perception, and in the left eye was reduced to detecting shadows and hand movements. The blood examination on April 12, 1938, disclosed hemoglobin, 13.8 mg.; red blood cells, 4,480,000; white blood cells, 4,750. The urine examination was negative. On April 20, 1938, examination of the right eye revealed a dilated pupil which reacted sluggishly. The disc was pale and yellow-white, with sharply defined border. There was a large temporal conus, with chorioidal atrophy, visible lamina cribrosa, small arteries, and full veins. The left pupil was small and reacted actively. The disc was pale, and the lamina cribrosa was visible, with a deep, wide physiologic cupping to the temporal border. The arteries were somewhat reduced in size. The field of vision is shown in figure 11. A diagnosis of arachnoiditis affecting the optic chiasm was made, but an exploratory operation was not advised at

Fig. 11 (Vail). Field of vision (A. H., case 6).

the time, since it was believed that the antiluetic treatment had not been sufficiently carried out.

Case 7. W. C., colored, male, aged 55 years, stated that his vision had been failing for about one year, but he had not realized how bad it was until he was examined. There was no history of chancre or of antiluetic treatment.

An X-ray examination of the skull was negative. On April 26, 1938, the blood Kahn test was positive to desensitized antigen only, and lumbar puncture showed a clear fluid with a pressure of 160 mm.; cells, 130; Wassermann strongly positive; gold curve positive; protein, 99 mg. Neurologic examination was negative. A diagnosis of syphilis of the central nervous system, taboparesis, and syphilitic chias-

mal arachnoiditis was made.

Ocular examination: Vision was: R.E., 4/200; the pupil was dilated and reacted sluggishly. The optic-nerve head was atrophied, white, and had a sharply defined outline and deep physiologic cupping; visible lamina cribrosa, and the arteries showed irregular narrowing, whereas the veins were of larger size than usual. Tension was 17 mm. Hg (Schiötz). Vision in the left eye was 20/100. The pupil was small

and reacted well to light. The disc showed the same findings as in the right eye, except that it was a little paler. The ocular tension was 19 mm. Hg (Schiötz). Blood pressure, 175/110. The fields of vision were as seen in figure 12. The patient was given antisyphilitic treatment, with the understanding that if further loss of vision or fields occurred, an operation was to be performed.

COMMENT

These patients all show the four essential points necessary to arrive at a diagnosis of syphilitic opticochiasmatic arachnoiditis: (1) Rapid loss of vision; (2) chiasmatic field defects; (3) mixed type of optic atrophy; (4) a history of or positive serology of syphilis. The diagnosis in case 1 was substantiated at operation. The other patients will be kept under close observation, and with their consent will be operated upon if there is no improvement under conservative treatment.

SUMMARY AND CONCLUSIONS

The literature on syphilitic opticochiasmatic arachnoiditis is reviewed, and seven additional cases, six of which are presumptive, are reported. Three of these cases were diagnosed by neurologists as of *tabes* or *taboparesis*.

A history of vascular lesions was obtained in two cases. The fields of vision showed defects that are considered to be characteristic of chiasmal involvement. Attention is directed to the mixed type of optic atrophy seen in all cases. The writer considers this type as one of the pathognomonic signs of chiasmatic arachnoiditis, and that it indicates a combination of simple atrophy and neuritis.

This study indicates that if neurosurgery is performed before it is too late improvement in vision may result. Hans

Reese, neurologic editor of the 1937 Year Book of Neurology, Psychiatry, and Endocrinology, in commenting on Hausman's paper, says that: "The more acute syndromes of this entity should be treated medically prior to surgical intervention, whereas a damaged optic chiasm with progressive field defects (low-grade reactivity in blood and spinal fluid) should be treated at first surgically and thereafter medically."

DISCUSSION

DR. RALPH I. LLOYD, Brooklyn: I am very much interested in Dr. Vail's paper, and particularly in the details of the autopsy and the operative findings in the anterior cistern about the chiasm. It seems to me that the specific cases considered as optic-nerve atrophy and ocular tabes are really of the type described by Dr. Vail. None of my cases has come to autopsy or operation, but perimetric examinations, if made early in the case, usually show that the original lesion first affects one nerve or tract, and later spreads to the chiasm. Progress is usually steady, and in some cases it is so rapid that the lesions must be vascular oc-

clusions. If the case is seen late, the white disc, shriveled retinal arteries, poor vision, and very small and irregular fields compel one to diagnose the condition as optic-nerve atrophy.

As an example of what early perimetry will reveal, I wish to report the case of a man in his late fifties, who lost the vision of one eye over night. He denied specific infection until the Wassermann reaction was reported as 4+. He exhibited Argyll Robertson pupils. The infection had occurred 35 years before the first ocular symptoms appeared. He had been under the care of an oculist who also did nose and throat work, and Van

der Hoeve had just published his article showing that the enlarged blind-spot is a regular accompaniment of sinus disease. The ethmoidal cells on the affected side were exenterated and the removed tissue sent to a pathologist, who reported hyperplastic rhinitis, which was considered a satisfactory explanation of the sudden loss of vision. The visual field of the apparently normal left eye showed that the superior temporal quadrant was missing, which, with the other eye already blind, positively fixed the site of the lesion at the chiasm, but indicated also that the lesion had originally affected one nerve first and then spread later to the chiasm. The remaining portion of the temporal field (inferior quadrant) failed gradually during the next four weeks, by which time there was one blind eye and a temporal hemianopia in the other: very typical of a chiasmal lesion and often seen in pituitary disease. After a short interval, the macular area of the functioning nasal half of the field faded out, and in another month the second eye was also totally blind. The knee jerks were normal until the patient was blind in both eyes.

Another case of this type began with very poor vision in the left eye in a man in his forties, who had had specific infection about 15 or 20 years before. The visual field of this eye showed a sectorial defect above, but the macular area was seriously affected, reducing the vision to a low figure. The superior border of the field of vision of the apparently unaffected eye soon began to disappear, and the conclusion was that the optic nerve of the left side had been affected first and that the lesion had later spread to the chiasm, but all of this change occurred on the inferior surface. I was not able to follow the case further, but it undoubtedly was of the type which, when seen later, exhibits an altitudinal hemi-

anopia but with very poor vision, since the macular area in these cases does not hold out as in cases of lesions behind the optic thalamus.

The general features of these cases are early pallor of the disc, steady—and often rapid—progress, early involvement of the macula, and, in the slower cases, bizarre visual fields. Many other nonspecific and nonpituitary cases that do not furnish a satisfactory etiology are much slower in development, with visual fields ranging from irregular binasal hemianopia to the contracted fields of optic atrophy, which can be explained only upon the basis of a similarly located disease, but up to the present time we have no exact details to settle this question. In older persons with similar visual-field defects, a satisfactory explanation is forthcoming. Considerable effort has been made to study these cases by autopsy and microscopy, with the result that the effect of pressure of sclerosed portions of the circle of Willis upon the chiasm, tract, and optic nerve is well understood. The anterior communicating artery has been found to cause a deep indentation in the superior aspect of the chiasm, and is the explanation offered for the early appearance of central scotomas because of the decussation of the macular bundles near the upper surface of the chiasm in the middle line.

Binasal hemianopia was shown by Herman Knapp to be the result of pressure of the posterior communicating arteries upon the optic tracts just behind the chiasm. Fuchs examined the brains of elderly persons and found amyloid bodies in the optic nerves with here and there patches of sclerosis. The amyloid bodies produced atrophy of the fiber bundles by direct pressure. In addition to these features, Fuchs found that the optic nerve was indented on the inner aspect, where it was pressed against the

sharp margin of the dura at the entrance to the optic canal, by the sclerosed ophthalmic artery.

The cases cited here occurred prior to the salvarsan period, and the question of the effect of arsenicals upon the optic nerve does not enter here. I hope Dr. Vail will give us more information on this subject, for we are sorely in need of exact knowledge concerning the pathology of the syphilitic lesions at the chiasm, and also as to the nonspecific and the nonpituitary cases.

DR. DERRICK VAIL, closing: I am grateful to Dr. Lloyd for pointing out the progressive effect on the field of vision in these cases, from the beginning to the end. Chiasmatic field defects are well known, and nothing new has been added by my contribution, except to point out the importance of this area in certain

lesions. Many other ramifications with which we did not deal might be considered; for example, the traumatic type of optico-chiasmatic arachnoiditis, and the suggestion that the optic atrophy of syphilis is due to the lesion arising in the chiasmatic cisterna affecting the optic nerve. Neither does the paper touch on the possibility that multiple sclerosis may have its origin in the chiasmatic area. It does not bring into the report the cases of Leber's disease that have been operated upon and in some of which arachnoidal membranes were found. It does take up, as Dr. Lloyd said, an entirely new field. I feel that Americans, in spite of the early work, particularly that of Cushing, have been a little remiss in not continuing their investigations. The French have taken over the field and have developed the subject extensively.

MANAGEMENT OF GLAUCOMA FOLLOWING CATARACT OPERATION*

B. Y. ALVIS, M.D.
Saint Louis

It is the purpose of this essay to deal with the therapeutic management of glaucoma as a complication of the cataract operation. There is probably no problem in ophthalmology that taxes our ingenuity more than this. There is none that requires greater vigilance nor greater persistence. There is no rule by which one may predict the length of time a case may take nor the end result. A single fortunate prescription or operation may bring permanent cure, or one may run the gamut of medical and surgical measures only to see the vision fade and the eye come to enucleation for the relief of the intolerable pain.

No extended description of the clinical entity under consideration is necessary, since an excellent thesis by Fox¹ was published only a year ago, giving a comprehensive view of the subject.

However, a brief review of the essential points may be worth while.

The term *postoperative glaucoma* is a broad one and includes cases differing widely in many clinical aspects, such as pain, congestive symptoms, time of onset relative to operation, effect on vision, and so forth, but having the one common essential feature; namely, increased intra-ocular pressure.

The cases divide themselves roughly into two groups: one, including those that arise soon after the cataract extraction or needling, usually exhibits signs of acute congestive glaucoma of greater or less

degree; the other, those that appear long, half a year or more, after the operation and usually follow a more or less quiet course resembling chronic or simple glaucoma.

Natanson² and others regarded the first group as comprising cases of secondary glaucoma arising as a result of operative imperfections, while the second, quiet group consisted of cases of primary glaucoma independent of the operative procedure.

As to etiology, there is general agreement that obstruction of the drainage angle is the essential causative factor. There are many operative and postoperative mishaps that may bring about such obstruction.

Vitreous entering the aqueous chamber, as noted by Bowman³ in 1865, may be the cause. The rupture of the hyaloid membrane in needling a secondary capsular cataract, or in the course of an intracapsular extraction, or when there is vitreous loss, becomes a predisposing cause of glaucoma.

Graefe⁴ noted rise of tension due to release of cortical remnants trapped in the collapsed capsule. He also mentioned ciliary irritation by traction on the zonula as leading to congestion and rise of tension. Plastic iritis with synechiae to the capsular remains has been the cause in many cases, as first noted by Priestley Smith.⁵

Adhesions of the lens capsule to the wound drawing the ciliary processes forward and closing the angle was demonstrated by Collins.⁶ Iris adherent to or in the wound has been described by many

* From the Department of Ophthalmology, Washington University. Read before the Saint Louis Ophthalmic Society, April 30, 1938.

and noted by all of us as a factor in causing glaucoma. Elschmig⁷ was perhaps the first to note an ingrowth of epithelium through a badly coapted wound, lining the anterior chamber and closing the angle. Dupuy-Dutemps⁸ mentioned a low-grade infection entering through imperfectly closed wounds as a source of ciliary congestion leading to rise of tension.

A scrutiny of these causative factors reveals each of them as a fault in technique. Dr. Hill Griffith asserted that glaucoma does not follow uncomplicated cataract extractions.

We have seen it follow in cases in which the operative and postoperative course was apparently uneventful, but one cannot be sure that no traction was exerted on the ciliary processes, leading to congestion and circulatory embarrassment.

One can be sure that an eye, after a clean-cut operation without adhesions of capsule or iris to the wound, with all cortex removed and incision firmly closed, is less liable to glaucoma than to other complications.

The pathology of postoperative glaucoma as revealed by microscopic study of enucleated eyes was carefully observed and described by Collins⁶ in 1890 and by many others since then.

Naturally, no eyes have been thus studied in which the glaucoma yielded to treatment. These are the characteristic findings:

The anterior chamber is generally shallow. The lens capsule is found adherent to the operative cicatrix in those cases in which the capsule was not removed. When no capsule is present, the hyaloid membrane may be adherent to the corneal scar. After iritis, the capsule may be "converted into a thick membrane by inflammatory effusion" with the iris adherent to the membrane. Blocking of the

angle of the anterior chamber occurs either by the root of the iris or by ciliary processes dragged forward by entangled shreds of capsule or vitreous. In inflammatory cases cell infiltration into the tissue of the iris and meshes of the ligamentum pectinatum is noted. The choroid may be much thickened by inflammatory infiltration. The retina may show cystic degeneration or occasionally detachment with fluid behind it. The optic nerve shows glaucomatous cupping except in the more recently inflammatory type, in which case it may be swollen and infiltrated with round cells. The vitreous usually is more fluid than normal and may contain remains of hemorrhages or inflammatory effusion.

That there is an inherent tendency to glaucoma in the majority of these cases must be seriously questioned, since in so many cases the fellow eyes are not especially liable to glaucoma whether operated on or not.

These pathological changes may bring about rise of tension in two ways. First, by increased formation of intraocular fluid as a result of drag on the ciliary body and processes; second, by blocking the angle of exit so that fluid is retained unduly in the cavum oculi.

That the presence of the capsular adhesions in the wound is not alone sufficient cause of glaucoma is shown by the fact that many cases in which adhesions exist show no rise of tension or have no attack until needling is done or some injury to the eye is suffered. Collins⁶ suggests that this added insult is necessary to start the increase in formation of fluid beyond the rate of drainage. The herniation of the vitreous into the aqueous chamber where it can obstruct the drainage angle seems a more probable cause of the rise in pressure.

The incidence of glaucoma following

operation for cataract ranges around 1 percent. Collins studied the records of 1,405 cases at Moorfields and found nine cases or 0.64 percent. A. Knapp⁹ reported 1 percent after primary extractions and 1 percent after discissions. DeGama Pinto¹⁰ reported 2 percent of 326 needlings. Rennecke¹¹ and Cavara¹² both found equal incidence after combined and simple extractions.

PREVENTION

Turning to the clinical management of cases it seems important to give some thought to prevention. Since the underlying causes and pathological conditions are direct results of faulty or ill-chosen operative procedures it would seem worth while to study the operation with a view to avoiding these errors.

1. The incision is the most important feature of the operation. It should follow the corneoscleral junction and should have a conjunctival flap above to aid in coaptation of the margins. It must be ample in size.

2. Avoid loss of vitreous. One cannot secure a neatly closed wound free of capsule, iris, cortex, and vitreous if the latter is protruding through the wound. The actual vitreous substance lost is much less important than the complications of wound closure.

3. The question of iridectomy, complete, peripheral, preliminary, or simple extraction has been argued pro and con. Statistics of large reported series are not definitely favorable to any one method. Without question an intact iris with the angle free offers the best protection against entanglement of vitreous, capsule, and cortex in the wound. The difficulties of delivering the lens through a round pupil and of avoiding iris adhesions or even prolapse often more than outweigh these advantages. Unless the pupil dilates

freely and well, I believe the complete iridectomy the safer procedure.

4. Intracapsular or extracapsular extraction presents another field of argument. Again it seems obvious that the complete removal of the lens favors an open angle and a wound free from adhesions, but if such a delivery can be accomplished only by an undue traction on the zonula, excessive pressure, and danger of vitreous loss, the gain is too dearly bought.

5. The toilet of the wound is a step of great importance in avoiding postoperative glaucoma. Great care in freeing the wound of all débris of capsule, iris, cortex, and clots in order to secure quick and accurate wound closure is entirely worth while. A large bubble of air injected into the anterior chamber at the close of the toilet is sometimes helpful in freeing the angle.

6. In capsulotomy a single, small, vertical cut through the membrane or a small inverted V opening made with a narrow knife needle with a tapered shank, so that vitreous will not be drawn into the corneal wound, should be made. The pitfalls here are the flooding of the anterior chamber with vitreous and the anterior synechia of hyaloid or capsule. A vitreous tag in the wound that easily escapes notice may lead to low-grade infection and congestion causing glaucoma.

The discission should be postponed until the eye is quiet. Use no atropine after needling unless iritis develops and the eye is soft.

7. The tension should be taken frequently in postoperative cases, and these should be kept under observation for some months if possible.

In general, prophylaxis is to keep the anterior chamber and filtration angle free and secure quiet postoperative healing, to avoid trauma to the ciliary body, and to

detect any tendency to a rise in tension before damage is done.

TREATMENT

The management of postoperative glaucoma calls for ingenuity and versatility and, above all, vigilance and persistence.

In the literature is recorded the use of practically every means that has been devised for the lowering of intraocular tension. No one measure has been attended with such outstanding success as to be considered a reliable cure for postoperative glaucoma. Where one fails, another may succeed. These measures may be divided into four general groups; namely, local medication, local physical therapy, general medication, and surgery.

1. Local medicaments are the miotics, the mydriatics, and the epinephrine preparations.

(a) The miotics, pilocarpine and eserine, appropriately head the list of local therapeutic agents. These are, after all, our most dependable agents. It is our practice to begin with pilocarpine 1 percent. Some cases respond at once with lowered tension. In most this response is only temporary and soon increasing strengths of pilocarpine (up to 5 percent) are necessary. If these do not aid, eserine is used, beginning with 0.5-percent solution. If eserine maintains lowered tension but must be used for a long period, an eserine sensitization develops. Eserine alkaloid in castor oil or in an ointment base may then be used. Even after surgical measures, one often must continue the miotics.

(b) The mydriatics—homatropine and atropine. In an occasional case with frank iritis these may reduce tension and lead to a cure, but must be handled with great caution.

(c) Epinephrine preparations—glauco-san, suprenen bitartrate (a 2-percent

solution or in ointment form) epinephrine 1/100, epinephrine 1/1000 as a pack are useful in certain cases of postcataract glaucoma. As a rule, in the acute or congested stage, the epinephrine preparations are not helpful. They may even cause severe pain and a further rise of tension. After the miotics have been used for some time, perhaps even after surgery and if the case has reached a stage with little congestion, when the tension remains up in spite of treatment, one may find this concentrated epinephrine surprisingly effective. One must be cautious at the beginning. Give the first treatment at the office or hospital where the tension can be measured after an hour or so. If the tension rises abruptly, a paracentesis should be done at once and eserine instilled. Even when effective, epinephrine is best used in conjunction with a miotic. I can, however, think of three patients who use only epinephrine 2 percent in water-soluble base, and only when they feel pain or blurring vision, indicating a rise of tension.

2. Local physical therapy includes heat, cold, and massage.

(a) Hot fomentations. Frequent and prolonged, this is the most useful of all nursing measures.

(b) Radiant heat. The infrared lamp, a simple 16 c.p. carbon filament bulb, any electric heating device may be the source. On ward service the infrared lamp is more apt to be applied as much and as often as ordered than moist heat which requires constant attendance of the nurse. Also radiant heat seems to penetrate deeper.

(c) Ice-cold applications. In occasional congestive cases cold may give greater relief from pain than heat, and should not be forgotten. Heat is more often useful.

(d) Massage of the eyeball may help to keep open an operative drain.

3. Constitutional medication.

(a) Ergotamine tartrate—intramuscular or oral administration of 1-mg. (1/60 gr.) doses has been recommended and seems to have been useful in some of our own cases.

(b) Calcium, gluconate or chloride. Both these medications are used for their effect on the sympathetic nervous system.

(c) Intravenous hypertonic solutions serve to withdraw fluid from the tissues and actually reduce intraocular tension. This effect is transitory lasting at most a few hours. This is useful as a preoperative measure.

(d) Purging and sweating fall in the same category and have not seemed worth while in our observation.

(e) Fever therapy may be useful where tension is secondary to uveitis. Typhoid bacilli are our choice, but milk or the hypertherm or hot baths may be used.

4. Surgical measures.

In the great majority of cases surgery is necessary. No one operation has found favor with any convincing majority of eye surgeons, but the following have the most success to their credit:

(a) Iridectomy. H. Knapp reported marked success in an early series of cases following simple extracapsular extraction. The general experience has not been so favorable especially in recent years.

(b) Cyclodialysis is considered the operation of choice in this particular type of glaucoma by Elschmig, Fuchs, Gradle, and others. It does serve to break up anterior synechiae of iris and capsule and doubtless is successful in many instances. It also is easy to do and does not mutilate the eye nor preclude subsequent operations by the same or other methods. Our own experience with this operation is not so satisfactory.

(c) Iris inclusion. This operation has grown largely in favor in recent years. Its simplicity and safety in execution and the permanency of drainage secured make

it a valuable measure. Even when the immediate reduction of pressure may be insignificant or nil, the ultimate result may be good.

(d) Trephining, especially if done in an area where the iris has been undisturbed previously is successful in a fair proportion of cases.

(e) Sclerectomy or iridosclerectomy (Lagrange) or Berens irido-corneo-sclerectomy are operations to be considered.

This by no means exhausts the list of operative and conservative measures that have been employed but includes most of those that we have used.

CASE REPORTS

The following cases are presented in some detail to illustrate what actually has been done. Some have rewarded our efforts with success; others have not.

Mr. F. X. M., aged 39 years, had had an extracapsular extraction of the left eye on February 19, 1931, with peripheral iridectomy. Very little cortex remained, but the postoperative course was rather stormy. In six weeks the vision with correction was 15/16. Three months after operation the capsule was still rather thick and a capsulotomy was performed. Some cortical material was stirred up, but the vision cleared to 15/10 in one week and remained good for two years, when thickening of the capsule lowered the vision, and a second Ziegler capsulotomy was done on May 24, 1934. The wound in the cornea did not heal for several days (probably due to vitreous shreds dragged into the wound by the needle), but in one week the vision was 15/12; the eye quiet and soft. Three days later, on June 2, 1934, an acute attack of glaucoma occurred. The tension was 47 mm. Hg (Schiotz), and was reduced by pilocarpine 1 percent administered every two hours.

Thereafter the course was as follows:

Date	Tension mm. Hg	Treatment
June 6	18	Pilocarpine, twice daily.
8	52	Pilocarpine, every two hours.
9	37	
11	52	Pilocarpine, 4 percent, four times a day.
12	14	
14	47	Eserine 0.5 percent four times a day.
15	10	
25	16	No medication; massage.
July 6	30	Eserine, once daily.
Aug. 1	Acute attack	Cyclodialysis by Dr. H. S. Gradle. Pilocarpine three times daily brought tension to normal until.
Sept. 7	37	Suprarenin jelly, 2 percent, instilled; tension rose to 47 mm. Eserine 1 percent three times daily.
8	30	
10	18	Twelve hours after eserine.
Oct. 13	20	Using eserine irregularly.
27	40	Eserine prescribed three times daily.
30	18 at 8:30 A.M.	Four hours later.
	37	Eserine three times daily.
Nov. 19	18	
30	37	Iridotaxis. Very little postoperative reaction.
Dec. 7	Normal to touch. Vision 15/12.	
15	+1 to touch	Eserine, 1 percent once.
26	22	

This patient has been seen occasionally since that time up to May, 1937. The tension remains normal with occasional instillation of eserine when he feels he needs it. The vision is normal as are the fields of vision.

Here, the iris inclusion seemed to be the solution.

As an illustration of those cases that refuse to yield to our best efforts, I cite the case of Mrs. E. D., aged 50 years, whose eye was needled two months after an extracapsular extraction. A considerable amount of cortical remains was liberated. There was an immediate rise of tension within 24 hours. In the two-and-a-half years that followed, this patient made 114 office visits; had 15 paracenteses of the cornea for temporary relief; had two iris-inclusion operations. She used pilocarpine and eserine solutions almost constantly besides hot packs, infrared heat, and massage locally; also saline eliminations, iodides, salicylates, gynergin, thyroid extract, and bacterial antigens. She had teeth, gall bladder, and sinuses

examined and treated. She had uveitis and arthritis as complications.

During this time the tension curve resembled a septic temperature chart ranging from 18 to 52, mostly about 30. At the end the eye was fairly quiet, tension 33 mm. Hg, and vision 5/60. The fellow eye remained normal throughout it all.

The next case is one in which persistent conservative treatment has been sufficient.

Mrs. W. H. S., aged 65 years, had a moderate rise of tension 14 days after intracapsular extraction. The operation and recovery were uneventful otherwise. Pilocarpine kept the tension low and in one month glasses were ordered; the vision being 5/5—.

Ten months later the vision was still 5/5, and the tension 47 mm. Hg. Pilocarpine 2 percent three times daily reduced the tension to a range of 16 to 20 and maintained it so with an occasional rise to 26 or 30. On January 7, 1936, the tension was 30 and suprarenin 2 percent in jelly was instilled, bringing the tension to 18 in 45 minutes. This preparation

alone used at night kept the tension low for the next six months, when it again rose to 33 mm. Hg. Pilocarpine three times daily was added and since then for one-and-one-half years, she has followed this routine fairly regularly. When she becomes careless and omits either the suprenin or the pilocarpine for a few times, the tension rises and the vision gets blurry. The visual fields and central vision so far have not been impaired. The disc is not pale nor cupped. The other eye has a mature cataract but is otherwise apparently healthy.

The following case was an apparently uncomplicated intracapsular extraction with iridectomy which ran a smooth post-operative course. There was a mild striped keratitis and, two weeks after operation, a small bit of vitreous was visible at one point in the wound. This healed soon and one month after operation the vision was 5/5. Three weeks later, however, there was some pain and redness, and the vision was 5/15. Tension was 18 mm. Hg. The next week the patient reported with a tension of 52 mm. Hg.; cornea steamy; and vision 5/25. There had been pain in the head and nausea and vomiting. Two-percent pilocarpine with hot fomentations reduced the tension, and vision again became normal within three days. The tension rose again during the next three weeks and suprenin jelly was used and ordered once daily with pilocarpine twice daily. There was no further rise in tension, and medication was gradually discontinued. When last seen, five months after the first rise of tension, the eye was quiet and tension 18 mm. Hg.

This was apparently a case in which the glaucoma was due to a low-grade infection which entered a small unclosed portion of the wound, leading to a congestion of the ciliary body which yielded to time, while the tension was held in

check through the combined influence of suprenin and pilocarpine.

A very recent case illustrates the necessity for a variety of therapeutic agents.

Mrs. W. C. B., aged 50 years, has had bilateral cataract extraction, extracapsular, with some adhesion of the capsule to the wound. The right eye was almost blind when trephining was done. The tension rose again in the right eye and shortly afterward in the left eye. The patient was highly nervous, and apprehension seemed to have brought about the attack in the left eye following a visit to her home oculist who had performed the operations. Eserine and pilocarpine were being used when I first saw her. The vision was ability to see hand motion in the right eye; 5/60 in the left; and the tension was above 100 mm. Hg.

Suprenin bitartrate 2 percent in jelly was used in the office; after a wait of an hour, the tension dropped to 40 mm. in each eye and the vision of the left had improved to 5/15.

After three days of hospital rest, where suprenin was used twice daily and pilocarpine 2 percent every two hours, the tension became and remained normal.

Two weeks later, following a visit to her home oculist who measured the tension as normal, the pressure again rose; this time medication and paracentesis failed to lower the tension permanently. Cyclodialysis was done, but the tension remained normal only a few weeks, even with medication, so an iridencleisis was performed on each eye. This time a slow rise in tension has been controlled by pilocarpine and eserine in the left eye; but the right eye, on her last visit, had tension of 40 mm. Suprenin was again tried, and in one hour the tension was 18.

The prognosis of postcataract glaucoma is not good. Of the series reported by Fox, about one third had good to fair

vision, one third had poor vision, and one third had no vision. This agrees in a general way with our own experience. With the thorough coöperation of patient and eye physician, we can save some vision, in most of these eyes, for many years; some of them can be cured; and some of them will be lost.

As a final word, I repeat these thoughts. The best treatment is careful cataract surgery to avoid the complications that give rise to postcataract glaucoma; but once the attack comes, the utmost versatility and perseverance in treatment is required.

METASTATIC SEPTIC ENDOPHTHALMITIS WITH RING ABSCESS OF THE CORNEA*

CASE REPORT, CLINICAL HISTORY, AND PATHOLOGIC ANATOMY

CHARLES W. TOOKER, M.D.

Saint Louis

Endogenous infection within the eyeball has been recognized as a disease entity for many years, but the interpretations of clinical observations and pathologic anatomy have varied considerably. Virchow¹ described endogenous infection of the retina in 1856, and stated that the choroid is not necessarily affected first. Purulent metastatic ophthalmia is a rapidly destructive disease, producing necrotic disintegration of the tissues within the eye, and usually terminating in panophthalmitis. A less malignant type of endogenous intraocular infection was first described by Roth² in 1872 and named "simple" septic retinitis. This observer wrote that septic retinitis is much more frequent in septic processes than is purulent metastatic ophthalmia, and that it is characterized by hemorrhages and small white, sharply circumscribed retinal foci which do not have a tendency to spread. He stated that the process is not due to emboli of pyogenic organisms in the retina, but to a chemical change in the blood dependent upon the sepsis. Probably those cases of metastatic ophthalmia which do not end in panophthalmitis are cases in which pyogenic bacteria do not enter the eyeball. Axenfeld,³ while first assistant in the eye clinic at Marburg in 1894, wrote his classic treatise on purulent metastatic ophthalmia. In about one third of his cases the disease was bilateral. In the unilateral cases he found septic emboli often deposited in the uvea, but in the bilateral cases the

retina was exclusively and predominantly infected. This simultaneous bilateral metastatic ophthalmia was usually the only demonstrable metastasis in the entire range of the carotid artery. He argued that it could, therefore, not have arisen from a general dissemination of coarse emboli-acting masses, since such masses must also have formed metastases in other places in the head and neck.

It seemed to Axenfeld most probable that in the bilateral as well as in a large number of the unilateral cases ocular infection occurred in the finest capillary branches, and that, therefore, there had been a general distribution of finely divided septic masses. Although bacteria were circulating in all branches of the carotid and ophthalmic arteries, selective localization occurred in the retina, and the orbitofacial distribution of the trunk vessel remained almost uniformly unaffected. He stated that a probable reason for the greater implication of the retina is the fact that the retinal capillaries are generally smaller than the choroidal capillaries, and that, unlike the choroidal capillaries, they are end arteries. He wrote that perhaps another reason for the involvement of certain capillaries, either of the retina or of the choroid, may have been the presence of areas of disease in the capillary walls favoring the lodgment there of microorganisms. Regarding the number of bacteria forming septic emboli, he recalled the fact that bacteria can increase in number after the death of the patient. Ulcerative endocarditis was found in about one third of Axenfeld's cases. Parsons,⁴ writing of purulent ret-

* Read at the Seventy-fourth Annual Meeting of the American Ophthalmological Society, at San Francisco, California, June 9-11, 1938.

initis, said: "It is only possible to conjecture why the retina should be so particularly vulnerable." Collins⁵ wrote: "Purulent retinitis may arise . . . from septic embolism in the retinal vessels. The retina becomes infiltrated with polymorphonuclear leucocytes, which make their way inward, collecting in large numbers between the retina and the hyaloid membrane and in the neighboring vitreous. . . . Septic emboli may also give rise to a nonsuppurative form of retinitis which is known as septic retinitis, in the same way as septic emboli may produce nonsuppurative forms of inflammation of the uveal tract."

In a more recent discussion of the subject, Schieck⁶ stated that in "simple" retinitis septica (Roth) there are no emboli of bacteria and no blocking of the retinal arteries. This disease seems to be caused by toxins, and the prognosis is more favorable than in cases of septic metastatic endophthalmitis. He wrote that usually purulent metastatic retinitis progresses so rapidly to a clouding of the vitreous and then to an involvement of the anterior part of the eyeball that panophthalmitis soon occurs. Schieck asserted that the staphylococcus was sometimes the cause of metastatic endophthalmitis following surgical interference in other parts of the body. Colonies of bacteria are found in the retinal vessels and in the vitreous. The choroid is spared probably because of its collateral circulation, but the retinal arteries are end arteries and become plugged with emboli. In discussing the question of bacteria and toxins, he remarked that if, by the term sepsis, one means the presence of germs in the blood, it is quite possible that in one case only toxic products and in another viable organisms may be present in the retinal vessels, and that in the same eye at different times there may be an alternation of these two elements. He

suggested also that the temporary state of immunity of the entire body and of the eyeball itself might be the decisive factor, and that variations in this fundamental condition might produce an exceptionally multiform disease picture. Metastatic septic ophthalmia and "simple" septic retinitis (Roth) could, therefore, be varieties of one and the same disease.

The case history which follows can properly be classified as that of a metastatic septic endophthalmitis or a purulent metastatic ophthalmia. A study of the pathologic anatomy in this case shows the presence of bacteria in the anterior chamber, the posterior chamber, and the vitreous. The retina, vitreous, ciliary body, iris, and cornea are infiltrated with pus cells. The choroid has not been involved. The ciliary body and the retina have been infected by septic embolism of their capillaries. The ciliary processes have been thoroughly disorganized and densely infiltrated with leucocytes. Toxins from the anterior chamber have infiltrated the cornea to produce a ring abscess.⁷ Ring abscess of the cornea has not been described in some of the reports of purulent metastatic ophthalmia, but it may not be of rare occurrence. In such cases the cornea is invaded by toxins and polymorphonuclear leucocytes, and a characteristic annular infection occurs, with necrosis of the posterior corneal stroma. Basil Graves⁸ has recently given an excellent description of this condition: "Ring abscess (peripheral annular infiltration), a serious purulent infiltration of the cornea, at first gray, then becoming yellow, may occur with rapid onset at the periphery of the cornea . . . in metastatic ophthalmia from focal sepsis. . . . The infiltration appears within a day in some cases, up to nearly two weeks in others, as a ring; usually complete, about 1.5 mm. wide, in most cases separated

from the limbus by an apparently clear interval which, in some cases, may be as much as 1.5 mm. wide. It is sometimes divided into two zones—an anterior in the stroma and a posterior between the stroma and Descemet's membrane. There is exudate in the anterior chamber of these cases, most of which go on to panophthalmitis. The probable explanation is that the cornea is secondarily attacked by a purulent iridocyclitis originating in local injury or in metastatic or general infections."

CASE REPORT

L. M., a male, aged 55 years, married, Italian, entered the De Paul Hospital on March 26, 1932, because of subacute suppurative otitis media of the right ear. The family history was unimportant, and his previous health had been excellent, except for repeated head colds. The general physical examination was negative. The routine ocular examination indicated no abnormality. Blood pressure and urine were normal. Stereo-X-ray examination of the mastoid regions "suggests inflammatory changes but no definite mastoiditis unless the development is very early." The patient's temperature remained normal. The leucocyte count was 6,250; Schilling differential count: Basophiles, 2 percent; eosinophiles, 4 percent; myelocytes, 0; juveniles, 0; stab cells, 8 percent; segmented cells, 47 percent; lymphocytes, 23 percent; and mononuclear leucocytes, 16 percent. The hemoglobin estimate was 75 percent. The treatment was symptomatic and palliative.

The patient was readmitted to the hospital on June 14, 1932, three months later, because of subacute mastoid inflammation on the right side. Blood examination: Leucocytes, 4,700; Schilling differential count: Basophiles, 0; eosinophiles, 1 percent; myelocytes, 0; juveniles, 0; stab cells, 7 percent; segmented cells, 68 per-

cent; lymphocytes, 21 percent; mononuclear leucocytes, 3 percent; hemoglobin, 80 percent. A simple mastoid operation was performed by Dr. T. Lawton, whose notes read—"very large mastoid with tip cells necrotic and filled with yellow pus. All other cells were involved, with a large amount of granulation tissue and pus extending into the zygomatic process. The lateral sinus was exposed and found normal." Cultures from the right ear on two examinations showed no growth after 18 hours. The general physical examination revealed some cardiac enlargement and a complete "block." The eye examination disclosed no abnormality. After an uneventful operative recovery, the patient was discharged from the hospital June 21, 1932.

On January 24, 1933, six months after the mastoid operation, the patient was brought to the hospital in a semiconscious condition, complaining of generalized pains, headache, and a sore left eye. His son stated that the patient had never regained good health since the operation on his ear, and that one week prior to his present admission to the hospital he had become acutely ill, with severe pain in his back and legs; that two days ago his left eye became inflamed, but that vision in his right eye continued good. On examination, Cheyne-Stokes respiration, cardiac fibrillation, and mental stupor were noted. During the three days preceding his death his temperature ranged from 101° to 106°F.; his pulse rate, from 75 to 105; and his respiratory rate, from 26 to 48 a minute. The urine contained much albumin, a trace of acetone, no sugar, many red blood cells, and some hyaline casts. His red blood count was 3,660,000, and his leucocyte count rose from 11,500 to 17,600. The Schilling differential count, made several times, finally gave the following picture: Basophiles, 0; eosinophiles, 5 percent; myelo-

cytes, 5 percent; juveniles, 14 percent; stab cells, 32 percent; segmented cells, 19 percent; lymphocytes, 25 percent. The estimate of blood sugar was 91 mg., and of blood nonprotein nitrogen, 60 mg. On two examinations the blood culture was positive for staphylococcus after 12 hours. The right eye appeared to be normal. Vision in the left eye was only perception of light. The conjunctiva was injected and mucopurulent secretion was present. The surface epithelium near the lower limbus was roughened. The cornea was generally infiltrated, but not steamy. The pupil was about half dilated and round. The iris was cloudy, and several yellowish-white nodules were embedded in it. Exudate covered the anterior capsule of the crystalline lens and obscured the ophthalmoscopic view of the fundus. Intraocular tension was 40 mm. (McLean). The patient died on the third day, and an autopsy was performed by Dr. R. Thompson.

Autopsy report. Considerable hypostatic congestion was present in the lungs, and a diffuse purulent bronchial pneumonia was found in the left lung. The heart was enlarged, and the mitral and tricuspid valves were covered with small, fibrous vegetation. The stomach and intestines showed no gross pathologic changes. Many fresh infarcts were present in the spleen, and both kidneys contained numerous small infarcts, with pitting and scars of the capsule and a few small abscesses. The pus in these abscesses was of a thick, creamy consistency. The liver also contained several small infarcts that were apparently of recent origin. The brain was removed, and sclerotic adhesions were found sur-

Fig. 1 (Tooker). Section through eyeball showing ring abscess of the cornea, swollen and disorganized ciliary processes, the accumulation of pus cells along the inner surface of the ciliary body and retina, particularly on the nasal side, and the considerable thickening of the retina just temporal to the optic nerve.

rounding the circle of Willis. The left eye was removed. On the left forearm, near the wrist, there was a large abscess, which was opened, releasing creamy, purulent material. The mastoid cells on the left were examined and found to be normal. Cultures from a kidney abscess showed staphylococci. Diagnosis: Septicemia.

Dr. Harvey D. Lamb, of the Department of Ophthalmology, Washington University Medical School, made the following report of the examination of the left eyeball:

Macroscopic findings: The eyeball was of normal size (fig. 1). The cornea showed a typical ring abscess (fig. 2), with the cellular infiltration involving centrally the anterior corneal lamellae. The anterior chamber was of normal

depth, and was filled with a finely granular detritus. The iris was largely necrotic, with much disintegration of the posterior pigmented epithelium. The ciliary processes were greatly swollen with inflammatory cells, and were necrotic (fig. 3). A thick layer of cellular exudate lay along the entire inner surface of the cil-

of the cornea (fig. 2) was characterized by a necrosis of the posterior layers of the substantial propria, limited peripherally and anteriorly by a thick zone of dense numbers of polymorphonuclear neutrophile leucocytes or pus cells. The necrosis of the cornea had involved practically all the posterior endothelium, but

Fig. 2 (Tooker). Section through one side of the ring abscess of the cornea, with part of the anterior chamber, iris, and of the posterior chamber. In the cornea there appears the necrosis of the posterior lamellae of the substantial propria, with the anterior and peripheral zone of pus cells. In the anterior chamber there occurs the detritus from degenerated red blood cells, pus cells, groups of cocci, and loose pigmented cells from the pigmented epithelium of the iris. From the necrotic iris, loose pigmented epithelial cells have gathered in the posterior chamber.

iary body, and became thinnest over the posterior end of the orbiculus ciliaris (fig. 1). Inflammatory material extended along the inner surface of the retina, being greatest on the nasal side and posteriorly. On the temporal side and posteriorly, the retina was very much thickened by inflammatory cells. The optic papilla was but mildly swollen.

Microscopic findings: The ring abscess

had had but little effect upon Descemet's membrane. As is typical of ring abscess, the necrotic mass or sequestrum in the cornea was widest or extended more peripherally in the most posterior corneal lamellae. From this widest, posterior margin of the necrosis the latter gradually slanted anteriorly toward the corneal center. In this case, however, the necrosis did not extend to the anterior surface of the

cornea. The central area of the cornea, involving about one third of the diameter of the cornea, and including about one third of the thickness of the cornea, was densely infiltrated with pus cells. In this part of the cornea, however, Bowman's membrane was destroyed, although the nuclei of the corneal corpuscles of the infiltrated anterior corneal lamellae still stained well. Where Bowman's membrane was destroyed, the anterior epithelium of the cornea had proliferated posteriorly to fill the shallow depression remaining. The latter is the essential process in the formation of a corneal facet. The anterior epithelium was everywhere atrophic, degenerated, and thin; in a few places it had entirely desquamated. Numerous pus cells lay between the anterior corneal lamellae. Peripheral to the necrotic part of the cornea, the pus cells lay in thick layers between the corneal lamellae, pushing the latter widely apart. Posteriorly and internally the infiltration with pus cells ceased rather sharply. Anteriorly, pus cells in considerable numbers had infiltrated the anterior epithelium. Peripherally, the zone of pus cells corresponded in width to about one half the thickness of the cornea. Toward the margin of the cornea, the pus cells ceased quite abruptly, although single pus cells were fairly numerous as far as the sclera.

The detritus in the anterior chamber was derived from red blood cells. Scattered throughout it were numerous small groups of cocci, degenerated pus cells, and loose pigmented cells from the generally disintegrated pigmented epithelium of the iris (fig. 2). The chamber angles were dilated by degenerating pus cells. On the nasal side, numerous red blood

Fig. 3 (Tooker). Section through the anterior part of the ciliary body, ciliary processes, chamber angle, and base of the iris. The ciliary processes are necrotic, swollen with degenerated pus cells and fluid exudate, and ruptured internally, producing a compact mass of exudate on their inner surfaces. The anterior-internal angle of the ciliary body is swollen to a less marked degree with red blood cells and pus cells. The chamber angle is dilated with pus cells and red blood cells.

cells lay in the chamber angle, whereas on the temporal side only a few red blood cells were observed. The source of this blood was plainly the anterior end of the ciliary body just external to the ciliary processes. Pus cells from the anterior chamber had invaded the filtration network and lay thickly between the trabeculae of the latter.

In the necrotic iris (fig. 2) there could be identified degenerated nuclei of chromatophores, the sphincter pupillae and dilator pupillae muscles, and thick-walled arteries. The pigmented epithelium of the iris lay in place only behind the pupillary zone on the temporal side. Here it was thickened considerably over the normal size and presented a little ectropion anterior to the margin of the pupil. On both sides, the pupillary end of the

sphincter pupillae muscle was also carried forward slightly. This thickening and ectropion of the pigmented iris epithelium, together with the ectropion of the sphincter pupillae muscle, must have been

Fig. 4 (Tooker). Section through flat or orbicular portion of ciliary body, presenting thick exudate of pus cells anteriorly, but very few posteriorly in the adjacent vitreous.

secondary to the atrophy of the iris that terminated in necrosis of that structure.

Just behind the iris, on the temporal side (fig. 2), there were numerous loose pigmented epithelial cells of the iris, intermingled with degenerated pus cells and a few small groups of cocci.

The lens exhibited some incipient cataract changes in the cortex adjacent

to the equator, as shown by swelling and segmentation of the lens fibers. The anterior epithelium presented a uniform, mild proliferation and degeneration. On the free surface of the capsule, anteriorly, lay thin layers of pigmented epithelium from the iris, and in the region of the equator, single pigmented epithelial cells from the iris, degenerated pus cells, and small groups of cocci.

The ciliary body was most unique, with a metastatic involvement of the ciliary processes as ocularly primary as that in the retina. The ciliary processes were generally necrotic and much swollen with degenerated pus cells and fluid exudate (fig. 3). For the most part, the processes presented ruptures internally, resulting in a compact mass of degenerated pus cells, red blood cells, and large clumps of cocci in the adjacent posterior and vitreous chambers. External to the ciliary processes the anterior-internal angle of the ciliary body was also intensely infiltrated with albuminous fluid, red blood cells, and pus cells. The capillaries of the ciliary processes were here undoubtedly the seat of the septic process. The ciliary body generally presented a moderate degree of edematous swelling. Small hemorrhages in the vascular layer of the ciliary body were numerous. Posteriorly, the latter contained a small number of pus cells. On the temporal side, internal to the anterior half of the ciliary body, there occurred large numbers of pigmented epithelial cells from the iris, both singly and in small groups. Between these pigmented cells there were large numbers of degenerated pus cells and numerous groups of cocci. Internal to the posterior half of the ciliary body on the temporal side, and internal to the orbiculus or flat portion of the ciliary body on the nasal side, a thick layer of loose degenerated pus cells (fig. 4) was seen. Internal to the latter, on the nasal side, occurred several

Fig. 5 (Tooker). Section through more swollen part of retina temporal to optic nerve, with numerous red blood cells, pus cells, and albuminous fluid infiltrating the inner retinal layers and large and small groups of cocci lying just internal to the internal limiting membrane of the retina.

small groups of cocci. The pus cells in the adjoining vitreous, opposite the posterior extremity of the ciliary body, were less numerous.

Of all parts of the eye, the retina was chiefly involved by the metastatic septic process. Almost every portion of the retina exhibited some degree of participation in this change, although the least amount of change occurred anteriorly on the temporal side. Here pus cells could be ob-

served coming from the small blood-vessels and mildly infiltrating the nerve-fiber layer of the retina. In the adjoining vitreous pus cells were few, except adjacent to the anterior extremity of the retina, where they had wandered posteriorly from the ciliary body. On the temporal side, posterior to the equator of the eyeball, the septic process within the retina became more pronounced. For about 6 mm. temporal to the optic nerve

Fig. 6 (Tooker). Section through part of retina just nasal to the optic nerve, where pus cells are entering the vitreous through a rupture in the internal limiting membrane of the retina.

the greatest degree of inflammatory swelling in the retina was seen (fig. 5). Between the optic nerve and the central or foveal area, however, the changes were slight. In the foveal region the retina was very irregularly swollen in Henle's fiber and the ganglion-cell layer by albuminous fluid and red blood cells. Temporal to the foveal area, the swelling was confined to the layers internal to the internal plexiform layer; this was due to infiltration with pus and red blood cells. Internal to this thickened retina, temporal to the optic nerve, comparatively few pus cells, but many small groups of cocci, were seen. On the nasal side, the septic process in the retina was more uniform. Almost everywhere on this side pus cells were seen coming from the blood vessels. The infiltration of the nerve-fiber layer with pus cells was moderate in degree from the ora serrata to the equator, then it practically disappeared behind the equator to become intense just nasal to the optic nerve. At the latter place could be observed ruptures of the internal limiting membrane by pus cells coming from the retina (fig. 6). On this side the retina was abnormally thick only near the optic nerve. Internal to the retina, between the ora serrata and the equator on the temporal side, lay comparatively few pus cells but numerous groups of cocci (fig. 5). Just behind the ora serrata, on the nasal side, the retina over a small area was necrotic and ruptured. This unused anterior end of the retina is always thin and atrophic. At this point, the purulent process was mild in degree, and therefore one is led to conclude that toxins from the numerous cocci in the adjacent vitreous had here destroyed the retina, perhaps after death. Near the

optic nerve and the equator of the eye, was slightly thickened with edematous fluid and infiltrated with numbers of loose plasma cells.

The optic papilla was somewhat swollen with edematous fluid. Its small blood vessels were seen to be the source of pus cells which were principally congregating in moderate numbers on the anterior surface of the papilla. No inflammatory cells were present in the optic nerve behind the cribriform plate, in its meninges, or in the subdural space.

Anteriorly in the vitreous, posterior and posterolateral to the lens, there were present a few degenerated pus cells and many collections of cocci. Posteriorly in the vitreous there occurred small numbers of pus cells, extensive networks of fibrin, and many groups of cocci.

SUMMARY

All the changes in the eyeball are secondary to the ocular primary foci in the retina and the ciliary processes. Emboli of bacteria must first have lodged in the capillaries of the retina and in those of the ciliary processes. It is unusual to have two distinct primary foci in the same eye, thus involving the retinal and ciliary vascular systems, although but a very small part of the latter is concerned. From the capillaries of the retina and ciliary body the bacteria easily enter the vitreous chamber. Here, by chemotactic action, they produce infiltration of the retina and to a small extent of the ciliary body with pus cells and the exudation of pus cells from the ciliary body, retina, and optic papilla into the vitreous. The ring abscess of the cornea and necrosis of the iris are, of course, secondary to toxins coming from the vitreous. As Axenfeld pointed out, a post-mortem increase of the bacteria would seem to be the most probable explanation of their large number within the eye.

COMMENT

The development of a septicemia six months after a mastoid operation would probably warrant the belief that the primary focus of infection was not the mastoid disease, and additional doubt is raised because of the fact that the cultures made from the mastoid at the time of the operation were negative. The patient was examined thoroughly, however, on several occasions, and no other focus of infection was discovered. It may be assumed, therefore, that the primary infection was probably in the mastoid cells. At the time of the patient's last illness the picture of septicemia was complete, and whatever the primary source of the staphylococcus septicemia the endophthalmitis may logically be considered to have been a complication of this septicemia. The vegetative endocarditis found at autopsy reminds one of Axenfeld's ob-

servation regarding the frequency of this condition in his series of cases. Clinically, the right eye was normal, but if the patient had lived longer this eye would also probably have become infected. The loss of the corneal epithelium in the lower part of the left cornea was no doubt due to exposure during the several days that the patient was unconscious. An unusual feature of the case was the presence of two primary ocular metastatic areas—one in the retina and one in the ciliary body of the same eye. The choroid contained some plasma cells and edematous fluid, but it was not otherwise affected by the purulent metastatic process.

I am indebted to the Laboratory for Ophthalmic Pathology, Washington University School of Medicine, for the preparation of the sections and the illustrations in this paper.

THE TREATMENT OF GLAUCOMA WITH SPLENIC EXTRACT

E. A. MILLER, M.D.
Saint Joseph, Missouri

Splenic extract was first used hypodermically in the treatment of eczema by Docents Mayr and Moncorps, of Munich, Germany, and their work was reported by their superior, Professor Leo Von Zumbusch.¹ These investigators attempted to supply the economy of eczematous patients with the secretion which their spleens failed to produce. They assumed splenic insufficiency to be the cause of this dermatosis, for the reason that eczematous patients and splenectomized animals both have eosinophilia. By means of this treatment they were able to cure long-standing cases that had resisted every other known form of treatment. In their opinion, the eosinophilia was merely an index of some underlying cause, as yet undiscovered.

Numerous articles soon appeared in French and German literature.² The results reported varied, but none of the writers were enthusiastic. This is due to the fact that clinicians obviously had not yet learned that the therapeutic efficacy of an organ extract is seldom, if ever, expressed by the number of grams represented by each cubic centimeter. Until a biologic standard is established for splenic extract, the results obtained by one clinician should not be contrasted with those reported by another unless both writers have used an extract made by the same laboratory, and, better still, from the same batch. The French writers especially, emphasized the fact that they use an extract of extremely high concentration.

In this country, Paul³ claimed that an

utes after the first injection; that some cases required no further treatment; and that most patients permanently recovered in one or two months. In one case, deafness, "caused by eczematous thickening of the cutaneous layer of the tympanic membrane," disappeared together with a similar involvement of the skin of the external ears. Three women's dysmenorrheas disappeared while being treated for eczema with splenic extract; "the annihilation of an allergic obstruction of the cervical canal, similar to the removal of such obstructions in the bronchioles in cases of asthma," is the explanation offered. In numerous cases, gastric disturbances, anorexia, and inability to tolerate certain foods disappeared; "coincident to recovery from 'eczema of the gastric mucosa' and eczema of the cutaneous surface" is the reasonable explanation. This observer appropriately asks: "Since eczema of the skin occurs without gastric involvement, if the gastric mucosa alone was the site attacked, could a gastro-enterologist make such a diagnosis?" "Such unlooked-for results," Paul states, "prove that eczema, like syphilis, is more than skin deep."

In consequence of a patient's permanent recovery from migraine while under treatment for urticaria, Paul concluded that the cephalalgia must have resulted from the pressure of the allergic edema of the brain against the rigid cranial walls. Later it occurred to him that a duplication of this phenomenon occurred in glaucoma, the only difference being that the angioneurotic edema, developing within the eyeball, meets the resistance of the inelastic sclerocorneal envelope.

The above theory sounded fantastic

when first expounded to me by this dermatologist, and my suspicions were intensified when he stated that this idea had been thrust among his meandering thoughts by his subconscious mind, when almost asleep after retiring. It happened that, at this time, I had a patient with glaucoma who was not responding to eserine, ephedrine, and pilocarpine, and would not submit to operative interference. I consented to this therapy after being thoroughly harangued by my colleague, as to how perfectly sure he was that glaucoma was simply intraocular angioneurotic edema, and how he had seen similar swellings on the cutaneous surface vanish in 20 minutes. He said that, at the very worst, the treatment could merely fail to benefit the patient, and that his statements were based on the treatment of over 300 cases during the preceding six years. I knew, moreover, that the patient would go blind if something was not done.

Magitot believed glaucoma to be a simple, or angioneurotic, type of edema within the eyeball. He thought this edema, in turn, was due to excessive capillary permeability. I gained this information from an exhaustive monograph by Luedde⁴ which confirmed what I learned from Paul. Since Magitot's papers⁵ appeared in 1929, and Paul had begun to treat dermatoses with splenic extract over a year previously, it is obvious that the idea that glaucoma is an intraocular edema must have developed in Paul's mind in the manner described by him. Had he merely learned it by reading Magitot's papers, he would have immediately suggested the trial of this treatment, instead of waiting five years before bringing it to my attention. It is needless to point out that by an attempt to deal with glaucoma as an allergic disease in the orthodox way, irreparable damage would be done while dawdling with skin tests and elimination diets.

Each day this patient, therefore, went to Paul, received his injection, and then came to me for observation of results. I am frank to admit that I hesitated to give the voluminous doses myself.* This patient had been taking 4 to 12 aspirin tablets every night and trying to sleep in a rocking chair because his pain increased on lying down. Immediately after the first injection there was a marked decrease in pain and reduction in intraocular pressure. Injections were given daily, and in five days the pain had completely disappeared. Treatment was started June 28, 1934, and the patient had fully recovered by July 30, 1934. During this time he received 12 injections. Within the following five months he had several mild recurrences, each of which quickly disappeared under one to three additional injections. The glaucoma involved his left eye, and he also had a cataract in his right eye. This patient was presented before the Buchanan County, Missouri, Medical Society on October 3, 1934, and a description of his case was subsequently published.⁶

The second case was of a 74-year-old woman, a former brothel keeper, about to die with cardiorenal disease, accompanied with severe edema. Paul gave her some of the first injections and she completely recovered from her glaucoma before her demise.

Such results completely destroyed my natural resentment to receiving instructions from a dermatologist, and thereafter I gave the injections of splenic extract myself. While the first treatments, given without Paul's supervision, were not unaccompanied with misgivings, I soon learned—as claimed by my colleague—that splenic extract is as harmless as it is effective. In arriving at this conclusion, I was not unmindful of Paul's statement

* It was 20 cubic centimeters of 40-percent splenic extract (Armour's).⁶

that he had treated over 300 patients for cutaneous and respiratory allergic diseases, during a period of over six years, without a single unfavorable reaction of any kind, before seeking my aid on account of his inability to diagnose glaucoma and evaluate the effects of this treatment.

Including the two cases just reported, I have treated 22 patients with splenic extract to date. Two of these showed marked decrease in tension, before deciding to place themselves in the hands of other ophthalmologists who performed iridectomies. In a third case, a peripheral iridectomy was performed for the reason that the increased tension returned as soon as treatment was discontinued, and despite the patient's having received numerous injections. The ultimate result, in this patient, was restoration of normal vision and tension.

Four of these patients had cataract with secondary glaucoma. Their prompt response to splenic extract proved that secondary glaucoma is amenable to this treatment. The advantage of reducing the tension in such cases before operation is obvious. Two patients presented themselves so late that partial optic atrophy was already present. A decrease in intraocular tension promptly followed treatment in both; but, of course, this did not clear up the scotomata in their fields.

The right eye of one patient had been operated on for glaucoma by a competent ophthalmologist, several years before I was consulted. Vision for form and light only was retained. The tension in the left eye, for which the patient consulted me, promptly subsided under splenic extract, and she has had no return of symptoms for two years. One patient's syphilis did not militate against prompt recovery under this treatment. Another patient's glaucoma quickly yielded to treatment, despite arterial hypertension and obesity.

A patient with swollen lenses, secondary glaucoma, and diabetes, who reacted poorly to eserine, ephedrine, and pilocarpine, responded immediately to splenic extract, although tension was permanently controlled and vision remained normal only after prolonged treatment.

A few particles of steel in a man's eyeball, acquired during the World War, caused a chronic secondary glaucoma. Two ophthalmologists advised enucleation. Splenic extract keeps the tension at, or near, normal if constantly used. He is a traveling salesman, carries a supply in his grip, and receives injections from physicians in the towns he visits. A patient who developed glaucoma after smallpox, completely recovered after four injections. One patient's tension slightly increased after the first injection. The second treatment reduced it to normal. She came to me very recently, and at this date the outlook is that she will completely recover under a few injections. This case is an illustration of Paul's "Jahrisch-Herxheimer-like reaction," hereafter described.

A patient, whose tension remained normal after several injections, had a recurrence each time he went on a spree. This case supports Paul's claim that alcoholic beverages completely nullify the effects of this treatment. In such cases the ingested alcohol neutralizes the secretion of the patient's own spleen after treatment has been discontinued. A case fully illustrating this fact is described in one of Paul's papers.⁷ Three patients discontinued treatment too early to enable me to decide if they had completely recovered. In each case, the tension came down promptly after the first injection. Fear of the hypodermic needle may have been the reason for their disappearance.

At the time Paul gave his first injection of splenic extract, February 25, 1923, methods of fractional extraction and the importance of biologic standardization

were not generally known. For this reason, most clinicians, and among them Paul, did not understand that an ampoule might contain an extract that was therapeutically worthless, despite its label's statement that it was obtained from a given organ. To use this dermatologist's own language, "It was owing to the fact that I reasoned, 'Splenic extract is splenic extract, and if I do not get good effects it is merely because I have given an inadequate dose!' Therefore, as a result of my ignorance of the possible absence of the curative fraction, I learned that the extract I was using was not only harmless but highly potent if given in a seemingly large quantity."

By cautiously increasing the amount injected, this clinician concluded that a dose of less than 20 c.c. is often ineffective, though 30 c.c. will cause no untoward reaction. He also learned that children seemed to have a tolerance for it out of proportion to their age. A newborn child will have no bad effects from a dose of 3 c.c.; 5 c.c. can be given to a 3-months-old baby, and a full adult dose to a 15-year-old child.

The extract we use is probably the weakest on the American market; it is the one used in the very beginning by Paul, and thoroughly deproteinized in order to obviate allergic shock. The voluminous dose required is fully compensated for by its clinical effects. We use a 10-c.c. Luer-lock syringe to prevent the needle from slipping during the injection, and a 22-gauge needle for the reason that one with a smaller bore requires too much time to draw up and expel the voluminous dose. Ten cubic centimeters is given in each upper arm because an edema, lasting several days, sometimes ensues if the entire 20 c.c. is given in one arm. Paul has given the extract four times intravenously; in three cases there were no bad effects, but in the fourth cases, a severe general re-

action, beginning one hour after the injection and lasting five hours, ensued. The patient made a complete recovery. An injection of 10 c.c. into each buttock prevented a patient from lying on her back the two following nights.

Injections are given at 48-hour intervals, unless symptoms recur sooner; in rare cases it may be necessary to shorten the interval to every 12 hours. As soon as symptoms indicate that the patient has fully recovered, a few injections are given at the usual 48-hour interval, as an insurance against recurrence, and then the time between the treatments is progressively increased, because we have learned this diminishes the likelihood of a return of symptoms.

During, or immediately after, an injection, a patient may faint. This is due to fright more often than to pain. Rarely a transient feeling of vertigo may supervene. For these reasons the patient should be either placed in the recumbent position, or seated on a table where such a position can be readily assumed. Elevation of the feet and a little time are all the treatment needed in any case. Indulgence in alcoholic beverages should be strictly forbidden. Careful inquiry should be made as to the nature of any liquid medicine the patient may be taking. The ingestion of even the smallest amount of alcohol definitely neutralizes the therapeutic effects of splenic extract.

Paul describes what he conveniently terms "A Jahrisch-Herxheimer-like reaction." This consists of a marked intensification of symptoms following the first and, perhaps, also the second and third injection. It is a favorable sign, for such patients almost invariably recover. According to his statistics, based on over 600 cases to date, it occurs in a little less than two percent of cases. In five cases of angioneurotic edema, in all of which there was recovery, this phenomenon occurred

in only one case. He points out that it is the one thing he greatly fears in glaucoma, for if an injection of splenic extract would produce such an effect in the eye, the patient's only hope would be immediate operative interference.

This treatment is in its infancy; only the results obtained by a large number of ophthalmologists, over a considerable period of time, will establish its therapeutic value. Laboratory study, for the purpose of trying to discover the principle underlying the action of splenic extract, and, if possible, to establish a biologic standard for it, should be undertaken.

CONCLUSIONS

1. Primary glaucoma is an angioneurotic edema within the eyeball, just as migraine is an angioneurotic edema of the brain. This is proved by the prompt relief of symptoms and reduction of intraocular pressure following the injection of a deproteinized extract of hog spleen.

2. The only reaction to be feared from this treatment is an intensification of symptoms, sometimes following an injection. Such reactions have been observed in cases of asthma, angioneurotic edema, urticaria, and eczema.

3. Continuation of this treatment will result in permanent recovery in most cases.

4. The danger of opening the eyeball under high tension is greatly reduced in cases demanding operation despite this treatment.

5. Therapeutic effects are not in proportion to the degree of the splenic extract's concentration, and favorable results can be obtained only if the extract happens to contain the curative element.

6. There is a crying need for laboratory investigation which might discover the physiologic action of this remedy, as well as a means of biologically standardizing it.

NOTES, CASES, INSTRUMENTS

A SPECIAL SOLVENT DISPENSER FOR THE REMOVAL OF ADHESIVE-PLASTER DRESSINGS

WARREN D. HORNER, M.D.
San Francisco

The removal of adhesive plaster from the skin is always a disagreeable task, particularly from a sensitive area like the face. In eye dressings this discomfort may cause squeezing, crying, or loss of confidence, particularly in children. It can be easily prevented by using a few drops of adhesive solvent, providing the solvent is at hand on the dressing tray. In my experience it usually is not. Benzene sponges are not efficient. Moistened applicators are better, but are seldom at hand. Application of solvents by a medicine dropper cannot be controlled, since the caliber of the pipette is too large to handle thin fluids.

It occurred to me that a solvent dispenser might be devised which could be conveniently kept on the dressing tray ready for use. After considerable experimentation with trial designs and various solvents, I would like to present the model illustrated. This consists of a stainless-steel container of convenient 3-ounce size and shape which is provided with a smooth spout containing a sensitive needle valve. It will deliver a thin solvent in just the right amount to separate adhesive from the skin, yet will not spill excess fluid into the eye nor down the face. It is equally effective in removing ordinary adhesive or the new cellophane Scotch tape.

The valve may be adjusted for different rates of flow and different solvents by turning the valve screw, and may be completely closed for carrying. The rate of flow of the solvent is faster when the dispenser warms from the hand and can be varied at will. Squeezing the sides of the

dispenser, as one would an oil can, also increases the flow momentarily.

As to solvents, I have used benzene, acetone, ether, and carbon tetrachloride. Ether is undoubtedly the least efficient and is a torture to anyone who has recently had an ether anesthetic. Benzene is inflam-

Fig. 1 (Horner). Solvent dispenser.

mable, burns the skin, and has an offensive odor. Acetone is better but is a powerful solvent and ruins duco or paint finishes, and is for this reason undesirable. Carbon tetrachloride is neither irritating nor inflammable and is our choice of solvents. Its odor may be disguised by the addition of one drop of oil of rose to the ounce. Carbon tetrachloride, which resembles ether, is not harmful in the amounts necessary to remove dressings. The commercial solution is quite inexpensive.

The solvent dispenser may be obtained from the Trainer and Parsons Optical Company, 228 Post Street, San Francisco, which has given me valuable technical aid in the development of the necessary experimental models.

PRISM SCALE FOR USE AT 50 CENTIMETERS*†**

CONRAD BERENS, M.D.
New York

Description of prism scale. This prism scale was constructed because of the desire to develop an indestructible scale the

markings of which were clearly visible and which could be used to measure the strength of strong prisms. It also seemed desirable to overcome the important disadvantage of most scales in that the distance they are constructed for is beyond the focus of many lenses to be tested. Results are often inaccurate with other

Fig. 1 (Berens). A, a prism scale for use at 50 centimeters. B, method of using the scale.

* Presented before the American Ophthalmological Society, San Francisco, California, June 9, 10, 11, 1938.

† Made by David W. Mann, Lincoln, Massachusetts.

** Aided by a grant from the Ophthalmological Foundation, Inc.

scales because no simple method for fixing the distance at which the scale should be used has been provided.

The prism scale (fig. 1A) is constructed of black bakelite, the actual scale and figures are of baked white enamel. A red-

enamel horizontal line serves as an indicator. A small metal cylinder is attached to the end of the distance cord, which may be wound around two pegs on the scale when not in use.

Method of using the prism scale. The scale should be well illuminated and placed 50 cm. from the observer, with the surface so arranged that the visual line is perpendicular to the scale. The metal cylinder at the end of the cord is placed against the prism or prismatic lens to be studied, which is held before the eye as depicted (fig. 1B). The displacement of the vertical line is read in prism diopters on the scale above the horizontal red line.

Advantages of prism scale. The advantages of this prism scale are that: (1) it may be used to test prisms of from .5 to 50^Δ, (2) it is especially useful because many lenses have a focal distance shorter than 1 meter, (3) the 50 cm. cord facilitates the accurate measurement of the prismatic deviation and, (4) bakelite is comparatively indestructible, light in weight, and easily cleaned.

IRIDOCAPSULOTOMY SCISSORS*†**

CONRAD BERENS, M.D.
New York

These iridocapsulotomy scissors, a modification of the scissors previously de-

* Presented before the American Ophthalmological Society, San Francisco, California, June 9-11, 1938.

† Made by the V. Mueller Co., Chicago, Illinois.

scribed,¹ have been found satisfactory for cutting secondary membranes and in performing iridocapsulotomy.

Description. The thin, narrow blades of the scissors are 14 mm. in length, and slightly curved. They are similar in shape to the Noyes scissors, except that both blades are pointed, and the spring cutting action is different than the scissors action of the Noyes instrument (fig. 1). The stationary blade is extended by an octagonal handle 14 cm. long; the second blade of the instrument is moved by downward pressure on a broad, flat arm, 48 mm. in length, which is slightly grooved at the end, so that the index finger will not slip while using the scissors. A strong spring is attached beneath this arm, and is carried across to the stationary handle, close to the blade joints. At this end, the spring has a small rectangular cut, enabling the shaft to slide over a small wedge when activating the arm. In the iridocapsulotomy scissors, which were presented in 1926, the movable arm is joined by an additional arm which penetrates through the center of the stationary handle. Both instruments have the duck-bill action and are always closed unless pressure is exerted on the arm, thereby making it easy to introduce and manipulate the scissors in the anterior chamber without muscular tension.

Method of using iridocapsulotomy scissors. After making a subconjunctival incision into the anterior chamber and perforating the membrane or capsule and

** Aided by a grant from the Ophthalmological Foundation, Inc.

Fig. 1 (Berens). Iridocapsulotomy scissors.

iris with a narrow hollow ground keratome,² the iridocapsulotomy scissors, with the blades closed, is entered into the anterior chamber. The blades are opened slightly upon reaching the opening made by the keratome in the membrane, one blade is passed under the membrane, the other remains on the surface of the membrane, and the blades are then permitted to close.

Advantages. (1) The iridocapsulotomy

scissors can be used through a smaller opening than can the de Wecker scissors, (2) the blades of the scissors completely fill the opening in the sclera made by the narrow keratome, thus preventing unnecessary loss of vitreous, (3) the scissors are more easily manipulated than the de Wecker scissors or the iridocapsulotomy scissors previously described.

SUTURE MATERIAL FOR OCULAR OPERATIONS*

DANIEL B. KIRBY, M.D.
New York

The author has devised new sutures for use in intraocular surgery, particularly in cases of cataract for conjunctival apposition. They have been used also for plastic cases. Another needle is being designed for sclerocorneal sutures. They are made by Davis & Geck Company, and are known as Product No. P 256 Special Eye Sutures. This product comprises a group of three individual sutures, each wound on its own reel, three reels being contained in one tube. Each suture consists of black

braided silk, size Six-0, length 18 inches, affixed to a specially designed one-quarter-circle cutting point atraumatic needle. The author has been pleased with the sutures. The needles are small, slender, sharp, have cutting edges, and do not turn in the needle holder. The suture material is single armed, thin but sufficiently strong. It is easily handled and tied and removed. The sutures can be supplied in double-armed needles. The product is economical, supplying as it does three sutures for use in the individual case, but being of sufficient length to be drawn through, cut off after being tied, and used again in other cases after resterilization. The sutures are 18 inches long, sufficient for three or four cases.

RECENT ADVANCES IN CHEMISTRY AS RELATED TO OPHTHALMOLOGY

DR. KARL MEYER of Columbia University said, after a general introduction about the role of chemistry in ophthalmic research, that he was dealing with two main problems, the metabolism of the lens and cataract, and the fluid exchange of the eye. A review was given of galactose cataract and dinitrophenol cataract. The hypothesis was put forward that the lens *in vivo* might be an obligatory anoxybiotic tissue, in which oxygen and oxidation cause denaturation of the proteins composing the lens.

The recent literature on fluid exchange of the eye was discussed. The evidence for the secretory origin of the ocular fluids was presented. The isolation and composition of a high molecular polysaccharide acid in vitreous and aqueous humor was stressed as being incompatible with the dialysis theory. Data on quantitative determinations of hexosamine in the aqueous humor of rabbits and cats were given. A report was made of the influence of eserine, which definitely increased the hexosamine and protein concentration of the aqueous; of atropine, which gave varying results; and of diosmin, which had no effect. A few analyses were given of the hexosamine content of glaucomatous and nonglaucomatous human aqueous punctates. In the cases investigated, including one of acute glaucoma, no increase in hexosamine or protein content was found. This finding

seems to oppose the vascular origin or the histamine theory of the increased tension.

SOME PHYSIOLOGICAL AND ANATOMICAL ASPECTS OF THE CORNEA AFFECTING ITS PATHOLOGY

DR. THEODORE L. TERRY read a paper on this subject which was published in this Journal (February, 1939).

ANISEIKONIA REVIEWED TO DATE

DR. WALTER B. LANCASTER read an interesting paper on the above subject. The following is an outline of the paper:

Causes: Anisometropia, asymmetrical convergence, unknown causes.

Consequences: (1) Effect on perspective, space perception, orientation (tilting plane). (2) Symptoms—namely, those of eyestrain—are like eyestrain from other causes.

Objections: (1) Any benefit from isekonic lenses is due to suggestions, psychotherapy. (2) Anisophoria is the probable explanation. (3) Since asymmetrical convergence produces large differences in size of the retinal images without discomfort, probably other forms of aniseikonia are taken care of without symptoms.

Reply: (1) Many, perhaps most, cases of eyestrain have a neurotic factor. Aniseikonia is no exception. That is not the

whole story, however. (2) Anisophoria is a phoria which varies in different directions of gaze like a paresis. A method of testing without changing the direction of gaze still shows the aniseikonia. Also the tilting plane cannot be accounted for by anisophoria though easily explained by aniseikonia. (3) It is easy to show on the Ames haploscope that asymmetrical convergence is automatically compensated because the optical image of the adducting eye is made larger by just the amount needed to correct the inequality of the retinal images which would naturally follow from asymmetrical convergence. It is a striking example of compensation. There are other ways of compensation that we do not know so much about. We know that some of them, when overtaxed, produce eyestrain that is relieved by eikonic lenses. Much harm has been done to the subject by overenthusiastic claims.

The steady progress that is being made by The Dartmouth Eye Institute in solving the many problems that arise from investigating the phenomena of binocular vision is convincing reason for confidence in their work.

SOME ASPECTS OF VISUAL ORGANIZATION

DR. KURT KOFFKA from the Department of Psychology, Smith College, Northampton, Massachusetts, read an interesting paper on the above subject. Dr. Koffka's problem was the connection between retinal stimulation and the central processes that correspond to vision. His thesis was that this connection is not a point-to-point coördination but that the total stimulus pattern supplies the boundary conditions for the organization of the central processes.

Dr. Koffka illustrated his thesis by a number of examples. He began with the pseudofovea of hemianopsia, relying on experiments by W. Fuchs (carried out

in the Frankfurt Institute of Gelb and Goldstein), which he has briefly discussed in his "Principles of Gestalt psychology" (Harcourt, Brace, 1935, on pp. 202ff.). He discussed the Aubert-Foerster phenomenon (see, for example, Ellis Freeman: What does a test of visual acuity measure? *Arch. of Ophth.*, 1929, v. 2, July, pp. 48-56), and added an experiment by Gelb discussed in his "Principles" on page 205, and one or two others. He then introduced the distinction of homogeneous and inhomogeneous stimulation and described in accordance with Metzger's experiments (see his "Principles," pp. 126ff.), that not all inhomogeneities are equally effective and turn to the laws of organization. Finally, he applied the same point of view to problems of eye movements (accommodation and fusion; see his "Principles," pp. 311 and 314ff.), and he ended with the problem why the objects appear at rest while we move our eyes.

DR. ROY E. MASON, *president*

MANAGEMENT OF GLAUCOMA FOLLOWING CATARACT OPERATION

DR. B. Y. ALVIS read a paper on this subject which is published in this issue of the *Journal*.

Discussion. Dr. William H. Luedde said because it is the problems of post-operative glaucoma which are under discussion, it appears reasonable to base conclusions on what can be demonstrated by examination of the ocular tissues. However, the percentages quoted concerning the incidence of this complication

(1 percent by Collins, 0.64 percent by Knapp, 2 percent by DeGama Pinto) may remind us of the 2 percent of malignant glaucoma reported by Von Graefe. These were also cases of postoperative glaucoma. They were in patients in whom the state of "absolute glaucoma" supervened after iridectomy for the relief of a previously existing glaucoma. The reaction to iridectomy in this special group resembles that reported by Kirwan after simple iridectomy for glaucoma in the eyes of patients suffering from epidemic dropsy. These were invariably made worse. These experiences seriously raise the question of the relation of the colloids of the blood plasma to the local ocular disease; a question not yet answered, but challenging further study. Kirwan found that filtering scars as provided by the trephine operation were successful in reducing intraocular hypertension in his cases. In two of his own patients the usual cataract extraction was complicated during the healing process by a slight iris entanglement at the extreme angle of the corneal wound with the formation of a filtration bleb under the conjunctiva. When he learned later that the brother of one of these patients had a cataract extraction followed by glaucoma and the sister of the other patient had become blind from glaucoma following cataract operation, he was not so sorry about whatever postoperative accident caused the iris prolapse, because both of the patients have retained vision of 20/20 or better for many years. This occurrence brings up the consideration of the statement by Dr. Alvis that a perfect operation for cataract does not seem to confer immunity from postoperative glaucoma, nor does it necessarily follow a less brilliant surgical technique.

Sometimes the cause of the secondary glaucoma is obvious, as it was in a young girl in whom absorption after discission

of a soft cataract was so perfect that excellent vision (20/20+ with correction) was achieved, but in one quadrant the iris had been doubled back upon itself by the first swelling of masses of lens substance in the anterior chamber. Gradually, a quiet increase in intraocular pressure began in this eye. The patient, with a curious mental twist, refused any further surgical correction and that eye became totally blind with glaucomatous atrophy. Surgical measures involving the iris usually can open only a small segment of the circumference of the iridocorneal angle, hence the postoperative use of miotics appears just as reasonable as for preoperative care in glaucoma. He has never sympathized with tests made to see if the patient could get along without any treatment after operation when instillations of a miotic at bedtime or twice daily might promote the safety and well being of the eye. For reasons noted in his recent résumé before this society, he always uses a strong miotic immediately after stronger solutions of epinephrin and has had no reason to regret it.

Inclusion operations appear to defy fundamental surgical principles in spite of their recorded success. Cyclodialysis, which offers no external or episcleral drainage, has never made a strong appeal to him. Since Ridley has demonstrated experimentally that the corneal limbus may be a factor in transfusion of fluids, he has secured striking general conjunctival edema when excision of corneal tissue was combined with iridectomy. Similar results were reported by Conrad Berens and the success of Otto Barkan's gonioscopic trabeculotomy may be explained in that way. Does Dr. Alvis use the bubble of air to raise up a cornea that collapses after cataract extraction? He has steadily avoided additional instrumentation in such cases and has failed to see any results that might indicate a greater

liability to postoperative glaucoma in such cases.

If, as was suggested, a low-grade infection and congestion can be caused by a tag of vitreous caught in the wound, then, also, the same reaction might be caused by extraocular foci of infection which apparently can produce these phenomena in eyes that have not been traumatized—surgically or otherwise. Thus, it would appear that every precaution, such as the preoperative elimination of focal infections, and so forth, may be properly applied to this class of cases as well as in any undertaking of intraocular ophthalmic surgery. This has been well demonstrated by Dr. Alvis's excellent résumé of his experience in postoperative glaucoma.

Discussion. Dr. B. Y. Alvis stated that he had used a bubble of air in raising a collapsed cornea and it may or may not have been advantageous. It made him feel better to close the lids with the wound margins already coapted.

REMOVAL OF INTRAOCULAR FOREIGN BODY AFTER 18 YEARS

DR. F. E. WOODRUFF reported that 18 years ago, on October 8, 1919, Roland M., aged eight years, presented himself with the following history: About four months previously he had been shot in the right eye with bird shot. There was no history of pain nor inflammation after the injury. The lens was completely opaque. A small scar in the cornea, and the iris wound, showed the path of the foreign body. Light perception and projection were good. No examination of the fundus was possible because of the opaque lens.

X-ray examination and localization showed a small foreign body in the globe, 2 mm. below the horizontal plane of the cornea, 11 mm. to the temporal side of the vertical plane of the cornea, and 15 mm. behind the center of the cornea.

The father was advised to bring the boy in from time to time to determine further action and treatment.

The patient did not return until March 31, 1931, reporting that he had not been under care or treatment since the injury in 1919. At this time (that is, 1931) the eye was deviating outward, light perception was good and projection only fair. The fellow eye was absolutely normal. Some of the lens substance had been absorbed and there was a fairly dense membrane with some iris adhesions. A needling was performed on April 2, 1931. The remaining lens substance absorbed but a second needling of the capsule was necessary. The membrane retracted back of the iris.

In 1933 the patient was reexamined. The right eye was quiet and the left eye, measured for a +0.50 D. cyl. ax. 90°, obtained normal vision. There were no symptoms whatsoever.

On September 15, 1934, the patient reported some difficulty with the right eye but this proved to be only a slight conjunctivitis which subsided under local treatment.

On September 21, 1937, the patient again presented himself with the history that for the last two years he had had intermittent trouble with his left eye, which was his good eye. There was some squinting, some disturbance of vision on the street and in picture shows. The eye was tender on pressure. He came for examination at this time not because of trouble in the eye but because of his wife's insistence (a doctor's daughter). The good eye was slightly irritable and tender but no impairment of vision could be demonstrated. X-ray examination of the right eye revealed a foreign body 11 mm. below the horizontal plane of the cornea, 3.5 mm. to the temporal side, 11 mm. behind the center of the cornea. On September 28, 1937, a scleral incision

was made at the site as localized. One lip of the wound was depressed and the shot fell into the spoon. The patient made an uneventful recovery.

This case is reported because of the length of time, 18 years, that the shot was in the eye before giving rise to symptoms referable to the foreign body. Since the foreign body was lead shot he thought that one could afford to wait at least for a time. The position of the shot in 1919 was such that it would have been a miracle if one had succeeded in getting it from its location at that time.

The gravitating of the shot into the neighborhood of the ciliary body was probably the cause of the disturbance of vision and slight tenderness experienced at the time the patient last presented himself. This may have been a sympathetic irritation which might have led to a sympathetic inflammation and loss of the good eye. Fear of this was the reason for interference.

Discussion. Dr. William F. Hardy said that Dr. Woodruff is to be congratulated on his ability to remove a nonmagnetizable foreign body from the vitreous without the use of forceps and consequent manipulation and disturbance of the vitreous. This fortuitous circumstance was occasioned by the change in the position of the foreign body from its original position to that 18 years later which brought it in close apposition to the sclera.

The history of foreign bodies in the vitreous is a rather sorry one. The seriousness varies, depending on a number of factors: (1) the size and shape of the penetrating substance, (2) its chemical nature, (3) the velocity with which it strikes the eye, (4) the site of penetration, (5) the presence or absence of infection, (6) the secondary changes which ensue.

A small object of inert chemical na-

ture hitting with moderate velocity, producing a clean-cut portal of entry, penetrating the sclera behind the ciliary body, and sterile in nature, should produce the least serious type of intraocular foreign body. Few fill all these requirements and the danger to the eye varies with each deviation therefrom.

Because of their size and shape some foreign bodies immediately and completely demoralize the ocular tissues. Others by their chemical nature produce so much reaction that the eye must eventually be destroyed. Lead, glass, wood, and stone are more or less inert. Copper, particularly, and iron are chemically active and destructive; both undergo chemical changes with deposition of their salts and staining of the tissues. Copper may lie dormant for a while and then may at any time start activity. A piece of copper within the eye is a veritable sword of Damocles hanging over the head of the unfortunate host. In favorable cases encapsulation of the foreign body may take place, which, in a sense, is a protective measure, but on the other hand makes removal more difficult and retinal detachment more likely.

Other factors being equal, a body of low velocity should produce less trauma than one of high velocity. The latter is likely to produce a double perforation, the outlook of which is very grave. Penetrations through the cornea usually mean traumatism to the lens. Objects lodging in the lens offer a good visual prospect, as the resulting cataract and foreign body may be successfully removed at one sitting. The presence or absence of primary infection is of the greatest importance. Fortunately, small particles of metal are usually sterile, due to the heat generated by the impact which gives rise to them. Many eyes are marked for destruction within 48 hours, due to the violent infection carried by the penetrating body.

One point which is always the subject of debate is the method of extraction of a magnetizable object: whether by the anterior or posterior route; whether through the original penetration or through a surgical one. This can apply usually only to foreign bodies in the vitreous chamber. In some cases a foreign body in the anterior segment can be removed with less trauma and manipulation through a surgical wound. As the foreign body in this case report was inert, any further discussion of these points is unnecessary.

The points of greatest interest in Dr. Woodruff's case are the following: (1) the length of time the foreign body lay dormant. This was due to its inert chemical nature; (2) the change in position making removal feasible; (3) the accurate localization; (4) the accuracy of the incision for removal; (5) that it was not encapsulated nor held by adhesions, and that it was in juxtaposition to the sclera, allowing it literally to drop into the operator's hand.

As to the presence of sympathetic irritation, he is a little skeptical unless the essayist has further data which he did not bring forth in the case report.

Dr. Roy Mason mentioned that there were a few cases in which he had removed nonmagnetic intraocular foreign bodies successfully, though the operation failed as far as sight was concerned. He had been successful in two vitreous cases, though there was a complete detachment of the retina following the operation. We are seeing more cases of nonmagnetic foreign bodies; new metals are being used, alloyed metals which are nonmagnetic. He believes our specialty has been neglectful in not giving a little more study to the removal of nonmagnetic foreign bodies.

BILATERAL GLIOMA

DR. M. L. GREENE presented a case of bilateral glioma in a baby four months

of age. One eye was in the glaucomatous stage, the other eye was preglaucomatous. There was no evidence of calcium deposits in the X-ray pictures of either eye. X-ray treatment of 400 R. was given to the right eye, which was then enucleated. There was no evidence of any cell destruction as a result of the X-ray treatment; in fact, an unusual number of mitotic figures were present. The left eye received a total of 1,200 R. and is still under observation, the tumor being very much smaller than when first seen. Two other cases of unilateral glioma were presented and discussed. There were no unusual features to these cases and they presented no calcium deposits on X-ray examination.

Discussion. Dr. Jule T. Elz said the eye enucleated in this case was placed in bromo-formol in order that some of the newer impregnating methods might be used, which he believes are necessary for a proper study of such tumors. Most of the knowledge of the histopathology concerning this group of neoplasms has been acquired as a result of the use of these staining methods and they should be used more frequently in order that the cell types present may be more thoroughly studied.

The term glioma retinae is a good one, especially if used in a generic sense and is preferred by Ewing. Dr. Elz favors the splitting of the main group of gliomas into three subgroups, depending on the predominating type of cell present; namely, the medullo-epithelioma, the retinoblastoma, and the neuro-epithelioma. He does not agree with those authors who seem to imply that all these tumors should be called retinoblastomas.

On opening the eye under discussion the vitreous cavity was almost entirely filled with a white, granular, friable mass. Sections of this tumor showed it to be a typical glioma of the neuro-epithelioma subgroup. The great number

of mitotic figures present was striking.

This case is of particular interest because the remaining eye is also involved and is receiving X-ray treatment. Reports in the literature indicate that this method of treatment has met with some success even though the glioma is considered radioresistant. In an article published in the November, 1936, issue of the Archives of Ophthalmology, Martin and Reese describe an X-ray therapy technique which seems to be a distinct advance in the handling of cases such as this one.

DR. THOMAS D. ALLEN, *president*

RELATION OF GLUTATHIONE TO GALACTOSE CATARACT

DR. JOHN BELLOWES and DR. L. ROSNER (by invitation) said that in a series of experiments galactose caused a decrease in the permeability of the capsules of beef lenses toward glutathione. Studies upon variation of lens glutathione with age were made. It was determined that lens glutathione of rats at birth is at the low value of about 50 mg. per 100 gm., it rises rapidly during the first days of life, reaches a peak of about 300 mg. per 100 gm., at an age of four months, then slowly declines. The glutathione concentration in the lens nucleus remains at a fairly constant low level, while that in the cortex fluctuates significantly with age. Feeding rats a diet high in galactose causes a loss of lens glutathione. However, when the animal is returned to a normal diet, the glutathione returns, showing ability of the lens to recover from incipient cataract. Even after development of cataract

the lens retains the ability to form normal transparent lens fibers in its periphery. Glutathione, however, cannot return to the opaque portion of the lens.

Discussion. Dr. L. Rosner (closing) said that upon feeding galactose the glutathione content in the lens decreased, and when the rats were returned to a normal diet the glutathione once more rose, indicating that the ability of the lens to produce this substance was retained.

He pointed out that it was difficult to study the capsule in life from the viewpoint of permeability. Two membranes are concerned, that of the capsule and the membrane of the lens fibers themselves. Thus a study in life of the lens capsule is complicated by the permeability of the lens fibers. If it were determined that a certain substance could not penetrate into the lens, would it be attributable to lack of permeability of the lens capsule or to impermeability of the membrane of the lens fibers? The experiments wherein the capsule was removed entirely, while open to the objection that they were not so significant as *in vivo* experiments, did get around the objection of possibly working with two different permeabilities.

In reply to Dr. Goldenburg's question, Dr. Rosner stated that there is no glutathione in the aqueous; it is contained entirely in the lens. The membranes of the body seem to have a selectivity to glutathione. In the blood, for example, it is in the red cells entirely; there is none in the plasma. It appears to be contained entirely in the cells of the body, not in the fluids. For that reason he believes that glutathione is probably manufactured in the lens itself and is not a matter of penetration into the lens.

CONGENITAL ABDUCENS PARALYSIS

DR. CARL APPLE read a paper on this subject which was published in this Journal (Feb., 1939).

Discussion. Dr. Sanford Gifford

thought that Dr. Apple had presented a very fine paper on this subject, to which too little attention was sometimes paid. It must be remembered, however, that there are a good many cases of congenital abducens paralysis in which the retraction syndrome is not a prominent feature. Some retraction might be found in all by careful study, but many cases had been seen in which it was not noticeable.

Tendon transplant had been successful in his hands. In cases without retraction, if strabismus was present, a good result could be obtained by transplant with tenotomy of the internal rectus. He had operated in nine cases. Two were acquired due to intracranial injury and the others were congenital, without a typical retraction syndrome. The outer half of the superior and inferior rectus was transplanted under the insertion of the external rectus, accompanied by tenotomy of the internal rectus. Possibly there were some bands in these cases, but that had not been investigated. In one case an over-correction was obtained, resulting in slight abduction. Only cases in which there was a primary convergence were brought to operation. The abduction which resulted from operation varied from 5 degrees to as much as 35 degrees. The only way such a result could be explained was not by the reëducation of the muscles but by the tone which these living-muscle slips gave to abduction. They held the eye in a certain position opposed by the internal rectus. When the internal rectus was relaxed in the attempt to abduct, they came into effect and actually caused the eye to rotate outward.

Cases of congenital abducens paralysis have been reported in which autopsy disclosed complete aplasia of the sixth-nerve nucleus; so it must be assumed that in such cases there is a central origin for the paralysis.

Dr. E. V. L. Brown asked if it would

be helpful to observe whether passive motion outward was possible under general anesthesia.

Dr. S. J. Meyer agreed with Dr. Gifford that operative interference is indicated and should at least be given a fair trial. He had operated on 18 patients with a good result in more than 50 percent. Some of the poor results occurred in cases in which there was marked secondary contraction of the internus muscle; so marked, in fact, that there was difficulty in performing a complete tenotomy of the muscle. He did not believe it made much difference whether lateral or medial halves of the superior and inferior recti muscles were transplanted. The external rectus muscle could be let alone if it were thought advisable. One must be meticulous in the dissection of the vertical muscles to be transplanted so that the sutures would not tear out.

Dr. Hallard Beard thought it always seemed fallacious to expect a portion of the adductor muscle to do the work of the abductor, such as one expected of the split portion of the superior and inferior rectus. One might hope to accomplish a good cosmetic position for the eyeball by such procedure, but hardly any restoration of function; and if one depended on the slight rotation of the eyeball by transplant of the tendon, then it would be better to sever the tendon of the externus if it were found to be a fibrous band. It would not be out of order either to slip back the insertion or sever the connection entirely from the eyeball so that it would not become reattached.

Dr. Carl Apple (closing) thought that Dr. Brown's suggestion was excellent. In 1926 Dr. Harold Gifford had stated that passive abduction should be tried in all cases. Passive abduction was attempted in the three cases reported, both prior to the operation and after tenotomy of the internus.

MONOCULAR PROTECTION VERSUS MONOCULAR OCCLUSION

DR. W. W. HOWARD read a paper on this subject which was published in this Journal (Feb., 1939).

Robert von der Heydt.

COLLEGE OF PHYSICIANS OF
PHILADELPHIA

SECTION ON OPHTHALMOLOGY

April 21, 1938

DR. ALEXANDER G. FEWELL, *chairman*

MUSCLE SPASM CAUSED BY EYEGLASSES

DR. LEO F. MCANDREWS presented the case of a man 41 years of age showing this interesting finding: as soon as the patient attempts to wear his glasses, a distinct, hard mass appears over the region of each mastoid. Under palpation this mass is evidently a contraction of the occipito-frontalis muscle. If the patient persists in wearing the glasses, the entire right side of the head and the right ear become painful and the neck becomes stiff. Removal of the glasses or firm pressure on the bridge of the nose causes the mass and discomfort to disappear. The condition has been present for about four years. The patient had a thyroidectomy three months ago, but he is still very nervous and emotionally unstable. There is no anatomic explanation for this condition. The probable explanation is that it is a neurotic manifestation associated with the toxic thyroid, and can be cured by appropriate psychotherapy.

Discussion. Dr. Walter I. Lillie said it was his impression that this is a spastic condition. Its duration of four years makes it very suggestive of a postencephalitic syndrome. When the man puts his glasses on he has a marked twitching of the eyelids. In a postencephalitic syndrome, especially those including respira-

tory changes, any sudden touch to any part of the body eliminates the attack. It would be interesting to follow this case and see if he develops a Parkinsonian syndrome.

OCULAR-MUSCLE PALSIES IN A CASE OF
TOXIC GOITER

DR. C. E. G. SHANNON made a supplementary report on a case of ocular-muscle palsies complicating toxic goiter. A preliminary report of this case was made at the meeting of the Section in April, 1937.

The patient, H. D., a milk driver, aged 47 years, was admitted to the Jefferson Hospital on April 2, 1936, with a diagnosis of exophthalmic goiter. His chief complaints were tremor of both hands, palpitation of the heart, bulging of both eyes, diplopia, excessive perspiration, and loss of weight. The blood count as also the Wassermann and Kahn reactions were negative. The basal metabolic rate was plus 45. Motility of the larynx was normal, with no apparent narrowing of the tracheal airway.

A subtotal thyroidectomy was performed, and the patient was discharged 10 days after the operation in good condition and relieved of all toxic thyroid symptoms aside from the proptosis and diplopia.

Briefly, the ocular history of the patient is as follows: In March, 1938, about a month prior to the removal of the thyroid gland, the patient first developed ocular symptoms consisting of diplopia, followed shortly by swollen and edematous lids and later by bulging of both eyeballs. The diplopia and proptosis persisted, but the lids became more quiet immediately following the operation. At the first examination of the patient, on December 4, 1936, the following notes were made: Vision, right eye 6/9 plus; left eye 6/9 mostly. Pupils were equal and reacted freely to light and consensually. The ten-

sion was normal in each eye; the media and fundi were negative. Both eyes were proptosed, the exophthalmometer showing 23 mm. on each side. The left eye appeared definitely deviated inwards and on a lower plane than that of its fellow. The Maddox rod showed an esophoria of 30 degrees and left hypophoria of 26 degrees. Diplopia was obtained in all the cardinal directions except in the immediate lower field—that is, about 12 to 14 inches from the eyes—indicating involvement of all the extrinsic muscles of the eyeballs. It was interesting to note that a wide separation of images at 20 feet diminished steadily as the light was brought toward the eyes until at a comparatively near point the diplopia nearly disappeared, suggesting a paresis of divergence. The power of accommodation was affected. The patient read J.14 at four inches on the right side and at five inches on the left side.

Various theories have been advanced in connection with the development of the exophthalmos, but so far none has proved entirely satisfactory. The etiology of muscle palsies in toxic goiter is still under discussion. The essayist made reference to the various theories so far presented by various authorities. In the preliminary report, an immediate operation to correct the muscular deviation was considered. In the discussion that followed, Dr. Zentmayer had suggested very wisely that an operative procedure should be delayed until the congestion and the proptosis had further subsided. He cited the report by Naffziger of cases of malignant exophthalmos with blindness in which enucleation was followed by death.

Two months later, under ether anesthesia, the superior rectus was tucked and the inferior rectus recessed. In addition, the external rectus was tucked and the internal rectus recessed. There was considerable reaction, as might be expected,

to these procedures but under ice compresses the swelling diminished, and binocular single vision was exhibited and still obtains.

A CATARACT SECTION REDUCING THE INCIDENCE OF IRIS PROLAPSE

DR. FRANK C. PARKER said the cataract operation today is frequently being made more and more complicated by conjunctival flaps and sutures. Instead of striving for simplicity and a short operative time, the opposite seems to be in vogue. In his own work he has found no reason whatever to make use of these embellishments.

Frequency of prolapsed iris in the simple extraction occurring up and in at about the 11-o'clock position in the right eye and at the 1-o'clock position in the left eye, raised the question as to the cause. The answer seemed to be that the drag of the knife as it is pushed through and pulled back with the upward push required to make the cut, is partly responsible. The structures—cornea and iris—are stretched peripherally, thereby weakening the iris fibers with resulting prolapse.

The incidence of prolapse has been greatly lessened by making the incision in a reverse manner to the customary section. As the knife is making the counter-puncture the heel is raised and the cut is made by pushing towards the pupillary center; and, as the knife is withdrawn, the point-end is raised, cutting as the blade is pulled back. In this way the force of the cutting results in a compression of the cornea and iris instead of peripheral stretching.

The manner of fixation is important in reducing the corneal stretching. The fixation forceps grasp the conjunctiva with a deep bite about 5 mm. above the upper limbus. The tissues between the cutting edge of the knife and the forceps above

the upper limbus are compressed, whereas when fixation is made below the whole cornea is stretched in the vertical meridian. If the cornea is stretched, it is reasonable to assume that the iris base is stretched as well. Large, bloody conjunctival flaps are not favored, simply a small fringe of conjunctiva on the lip of the wound is desired.

Discussion. Dr. H. Maxwell Langdon said he wondered if Dr. Parker has considered a bridle suture under the superior rectus. It seemed to him that it would not be quite so much in the way as forceps in this position, and it would give him very good counter pressure against the knife. He did not see just where reversing the usual procedure in making the cut exerts less drag on the cornea. If the point or the heel is raised first, the other portion of the knife must make the next step in the procedure and it seems to him that the drag would be about the same.

Dr. Francis Heed Adler asked Dr. Parker if he had noticed any decrease in the amount of striate keratitis in his cases, using the present method of making the section. He cannot understand how this method would diminish the incidence of prolapse of the iris, but he can believe that it might materially reduce the amount of striate keratitis.

Dr. Parker in answer to Dr. Langdon's question said he had never used the bridle-suture fixation, as it requires a pull upon the globe before fixation comes into play. With an open wound, such as is present following extraction, this does not appeal to him. Again, forceps fixation does away with any "swaying" of the eyeball. Further the placing of this suture adds to the operation and consumes time.

He had not seen any striate keratitis for some time past. Whether or not this can be attributed to the lessened "drag" in this incision he was not prepared to say. However, one might easily deduct that

with diminished stretching of the cornea, striate keratitis would be kept at a minimum.

THE CLINICAL SIGNIFICANCE OF THE RETINAL CHANGES IN LEUKEMIA

DR. GLEN G. GIBSON said his paper was a report of the laboratory and retinal findings of 22 cases diagnosed as various kinds of leukemia by the medical department of Temple University Medical School. Based on the findings in these cases a discussion of the diagnosis and the prognosis is given. Emphasis is placed on the retinal veins being darker and fuller than normal in 17 of the 22 cases. In general, there seemed to be a relationship between the amount of retinal hemorrhages and the clinical condition of the patient. In general, the patients who had the lowest red-blood-cell count had only a moderate degree of retinal hemorrhage and those with the higher red-blood-cell count had no retinal hemorrhages. It was suggested that it might be more advantageous to direct therapeutic and investigative procedures toward the factor of anemia instead of towards the leucocytosis.

Discussion. Dr. Gibson in answer to Dr. Adler said in observing these cases one gets the impression that the white centers are due to a collection of serum and hemorrhagic debris rather than to a nest of white blood cells surrounded by red blood cells. He regretted that he had no microscopic confirmation of this impression.

EXTERNAL ORBITOTOMY

DR. EDMUND B. SPAETH presented a moving-picture demonstration of the external-route orbitotomy without bone resection for the removal of retrobulbar tumor.

Directors: EDWARD JACKSON, President, LAWRENCE T. POST, Vice-President, Dr. F. E. WOODRUFF, Secretary and Treasurer, WILLIAM L. BENEDICT, WILLIAM H. CRISP, HARRY S. GRADLE. *Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to Dr. Lawrence T. Post, 640 S. Kingshighway, Saint Louis.*

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver.*

Subscriptions, applications for single copies, notices of change of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 640 S. Kingshighway, Saint Louis.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

DICTATORSHIPS, DEMOCRACIES, AND POSTGRADUATE MEDICAL STUDY

The Greek word "turannos" (tyrant) meant an absolute ruler, and not necessarily one who abused his power. There have been a few benevolent despots, but there are not many exceptions to the rule that when the power of an individual or of a group is uncontrolled it will sooner or later be abused; that is, it will be exercised without regard to the rights of others.

It is probable that great political power has never been entirely free from abuse. No individual or group possesses infinite wisdom and fairness. The hysterical vagaries of the ignorant mob are notorious,

yet the rights and liberties of the general populace are in the long run safer under democratic than under autocratic, or "tyrannical," forms of government.

Today it appears that the greatest loss resulting from the World War is the sacrifice, in several civilized countries, of those great measures of human liberty which had been achieved step by step in the course of generations.

Exhausted by four years of murderous and ruinous struggle, and by the ensuing financial chaos, the democracies seem to have lost the spirit of resistance to usurpation and absolutism. Excesses such as disgraced the Middle Ages have been tolerated almost without a murmur by peoples who were regarded as in the van-

guard of civilization. Beneath the veneer of material progress man the brute appears in all his primeval crudity.

It is hardly surprising that a tyrant should make his own interpretation of scientific facts and values. His dogmas come first, and facts are grouped or distorted to suit those dogmas. Facts that fail to harmonize with his alleged principles must be ignored or falsified.

In the wonderful hygienic exposition of a large European city, the scientifically-minded traveler is shocked but not altogether surprised to find that the pure science of one section of the great building has been replaced by blatant, hideous, and unscrupulous exhibits whose purpose is to prove the purity and superiority of the Nordic and the degradation and inferiority of those who are denied that appellation.

Since absolute rulers do sometimes display liberality of thought, it would be wrong to argue that tyranny is always incompatible with scientific progress. But suppression of all independence of thought and action cannot fail to inhibit the scientific spirit.

Apart from more material considerations, one priceless advantage of living in a democratic community is the feeling that one may express himself according to his honest convictions and may hear or read a free expression of the opinions of others, without restraint of censorship or danger of political persecution. In some European countries, not even the traveler from another land may enjoy these privileges; and the visiting tourist suffers from an uneasy sense of restraint and concealment. No amount of hospitality displayed by those among whom he travels can overcome these barriers. Newspapers report only what they are allowed to report. Newspapers and citizens alike believe (to outward appearance) only what they are allowed to believe. After such an experi-

ence, to cross the boundary into a country that is still democratic is to escape from a mental and spiritual prison.

In spite of the rapid development in facilities for postgraduate education in the United States and Canada, many medical pilgrims from this country still visit the old clinical institutions of central Europe. But under present conditions it may be doubted whether such cities as Vienna will maintain their former prestige as centers for postgraduate study in the various fields of medicine.

We are told that in the stress of preparation for another great war, one of the dictator countries has recently curtailed the undergraduate period of medical study, as well as cutting one year from the length of the "gymnasium" or preprofessional course. A certain significance may also be attached to changes in the field of medical journalism, due perhaps partly to political and partly to economic causes.

The combination of Graefe's *Archiv für Ophthalmologie* with *Archiv für Augenheilkunde*, both journals of very limited circulation, may probably be dismissed as a mere matter of economy. Removals of journals from one country to another are more likely political in character. What was formerly the *Zeitschrift für Augenheilkunde*, an excellent monthly founded forty years ago by Kuhnt and Michel, is now published as "*Ophthalmologica*" at the Swiss city of Basel. It prints essays in English, French, and German, and its list of editors contains prominent names from various civilized countries, not including Germany.

Another medical periodical, *Ars Medici*, has moved its place of publication to Basel from Vienna. In that great Austrian capital it served for sixteen years as a sort of publicity agent for postgraduate medical teaching facilities. It is a modest monthly, "the only medical journal in the English language appearing on the Continent,"

and presenting usually one original article and a large number of well-written abstracts from miscellaneous medical journals. It had formerly an official connection with the "American Medical Association of Vienna," an organization having no connection with the American Medical Association, but serving as a center for contact and information among English-speaking physicians who were attending the Viennese schools, hospitals, clinics, and privately conducted classes.

This little journal announces that one of its major purposes is to furnish information to physicians seeking postgraduate work. "Five faculties of as many medical colleges of the universities Basle, Berne, Geneva, Lausanne, and Zurich . . . are now prepared to teach you if you desire to specialize or do postgraduate work in any and all branches of medicine." It is added that all courses will be in English. The name of Professor Alfred Gigon, Klosterberg 27, Basel, Switzerland, is given as chairman on the faculty committee, to whom correspondence relating to medical courses in Switzerland may be addressed.

The five Swiss universities mentioned have produced many famous names in medicine. Switzerland is the world's greatest holiday resort. It is still one of the freest countries of the world. Foreign study is usually combined with a good deal of sight-seeing and enjoyment of other recreational facilities. Think of the opportunity for such combinations afforded by Basel, south of which lies a rolling country at least as attractive as the Black Forest although less advertised; Bern, the Swiss capital, a little way north of the Bernese Oberland; Geneva, astride the west end of Lake Geneva and within easy distance of Mont Blanc; Lausanne, further along Lake Geneva; and Zurich, commercial capital of Switzerland, location of this year's Swiss national exposi-

tion, and scene of Vogt's work on the slit-lamp. If you desire to go abroad for postgraduate study, why not choose Switzerland?

W. H. Crisp.

TREATMENT OF GLAUCOMA

When ophthalmic surgeons first recognized glaucoma as a cause of terrible pain and permanent blindness, these effects seemed unavoidable. When Graefe noticed that iridectomy lowered intraocular tension, and reported some cases cured by the operation, it was at once accepted as the one cure of glaucoma. Since then, other operations—division of the ciliary body, iridotomy, trephining, iris inclusions, the Lagrange operation, cyclodialysis, Holth's punch operation, and opening of Schlemm's canal—have been brought forward as curative of the disease. These operations have all been founded, mainly, on the assumption that glaucoma was caused by mechanical obstruction to the outflow of fluid from the eyeball, and was to be relieved by opening a new channel for such mechanical outflow.

We cannot believe that the regulation of intraocular tension is purely a mechanical process. The regulation of intraocular tension must be intimately connected with the nutrition and metabolism of ocular tissues. But our knowledge of the physiology and biochemistry of nutrition for the different tissues of the eye is scanty. It must be supposed that the endothelium of the capillary blood vessels and the glass membranes of the eye—Bowman's, Descemet's, the lens capsule, and Bruch's—may play a part in these processes as well as the composition of the blood serum and the height of the blood pressure.

An approach to this side of the glaucoma question is suggested in the use of splenic extract, as described in this issue of the Journal, page 536. The facts al-

ready observed would suggest the production in the spleen of some biochemical product capable, either directly or indirectly, of influencing the intraocular pressure. What this substance is, and how it acts, we do not know. But each use of it to reduce the intraocular pressure in a case of glaucoma becomes a physiological experiment, to be observed and recorded, with associated phenomena, as capable of throwing possible light on the essential process of intraocular tension and its pathological increase.

The operations that have been done for glaucoma, and each urged as superior to the others, are so varied in their plans and execution, and are supported by such a wide range of theoretic explanation of glaucoma and its relief, that we must realize the treatment of glaucoma is quite empirical; and anything that as an empirical treatment seems to give relief must be considered worth trying. It would justify careful observation, with the presumption that it has some value. Under these circumstances, even if we doubt the theoretical explanations of such cures, we have the right and duty to make use of the new remedy in those cases where there is a doubt of the efficacy of the remedies we have previously relied on.

The miotics have been widely tried for glaucoma, and generally with benefit. Laquer, of Strasburg, for more than five years kept his own eyes from any permanent loss of vision by increased tension, before he had them operated on (iridectomy) by Horner. After that he lived a quarter of a century using his eyes, as he had done before, without any recurrence of glaucoma. In occasional cases of undoubted glaucoma, the use of miotics has brought about a return of the eye to health, with no recurrence of the disease subsequently. The common belief that glaucoma means either operation or blindness is not correct. We must admit that

there is something beside operation that can cure glaucoma. To find out what this something is, is a proper subject for investigation and experiment. What we now know of the actions and power of the endocrines makes it reasonable to think that something formed in the spleen may be what is needed to reduce intraocular tension. Only experiment can decide whether this is, or is not, true.

It is not true that a certain increase of intraocular tension is safe for all eyes; or that pressure above a certain point is sure to damage a particular eye. Eyes with less than 20 mm. of mercury pressure undergo atrophy of the optic nerve, with deep, glaucomatous cupping. Other eyes with tension of over 30 mm. go on for years without any impairment of vision or of the visual field. We do not recognize brief changes of intraocular tension without evidence of damage to visual function. We need more knowledge of the physiology of ocular nutrition and of intraocular pressure to furnish a rational basis for the therapeutics of glaucoma. Meanwhile, every measure found empirically to be of some benefit should be tried. It should be studied to find its relative efficiency and indications and to enrich our armamentarium for the future.

Edward Jackson.

BOOK NOTICES

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. Edited by Dr. Bernard Samuels. Clothbound, 370 pages, Philadelphia, Wm. F. Fell Co., 1938, volume xxxvi.

The seventy-fourth annual meeting of the American Ophthalmological Society was held in San Francisco. Dr. Frederick Tooke of Montreal was elected president, succeeding Dr. F. H. Verhoeff. There are

25 excellent papers in this volume: 11 deal with clinical and experimental pathology, 3 are on surgical procedures, and 2 on aniseikonia.

Dr. Wm. H. Crisp advises the use of cycloplegics in refraction and the full correction of the reportive error. The discussion of this paper by Drs. Jackson, Gradle, and Lancaster reveals rather marked differences of opinion on the subject of refraction. Dr. Joseph L. McCool reviews the literature on tumors of the lacrimal sac and records a case of mixed tumor of the sac. Dr. Bernard Samuels, from a review of many proved cases of sympathetic ophthalmia, found that in 3 percent there had been a preceding panophthalmitis. The extreme importance of the correct microscopical diagnosis of sympathetic ophthalmia is emphasized.

Dr. Charles Tooker reports a case of metastatic septic endophthalmitis with ring abscess of the cornea. Dr. Arnold Knapp presents a case of orbital hyperostosis in meningioma. The ocular manifestations of brucellosis (Malta or undulant fever) and the history of the disease are reviewed by Dr. John Green. The incidence of the disease is high; the ocular symptoms and pathology resemble tuberculosis. The diagnosis of brucellosis is made by skin tests and blood agglutination tests. Dr. Derrick Vail records the syndromes of opticochiasmatic arachnoiditis with optic-nerve atrophy and blindness. The study indicates that neuro-surgery in early cases may be of value in preserving vision. Dr. Albert N. Lemoine reports an optic-tract lesion associated with infection of the sphenoidal sinuses. Dr. John Wheeler describes a new technique for correction of spastic entropion by transplanting the orbicularis muscle. Dr. Paul Chandler recommends inferior iridotomy in cataract extraction on eyes affected by iritis, cyclitis, or glaucoma.

The history of American ophthalmology from 1908-1915 is given by Dr. S. Judd Beach. Dr. Arthur Bedell records three cases of traumatic retinal angiopathy. Clear photographs of the fundi are shown. Dr. Phillips Thygeson describes the Carrel technique of tissue culture and reports the cultivation of human conjunctival and corneal epithelium. Dr. Trygve Gunderesen records the results of auto-transplantation of cornea into the anterior chamber. The endothelium thrives; the stroma survives and the epithelium disappears. Dr. Parker Heath and Dr. C. W. Geiter report physiologic and pharmacologic reactions of iris muscle by an autographic method. There are two papers on aniseikonia, one by Dr. Lancaster on its causes and consequences, and one by Dr. Conrad Berens, who reports that of 836 patients examined for aniseikonia 438 were given iseikonic lenses, and of these 73 percent were improved.

Dr. Gordon M. Bruce records an unusual type of retinitis found in three cases of dermatomyositis. The lesions were confined to the posterior pole of the eye and consisted of scattered grayish-yellow areas of exudates resembling cotton-wool patches. Dr. Arlington C. Krause reports on the proteins, lipids, and water-soluble extractives in fresh bovine optic nerves. Dr. P. J. Leinfelder presents the pathological findings in retrograde ganglion-cell and nerve-fiber degeneration following section of the nerve anterior to the chiasm. Dr. William Stokes, from a study of experimental keratitis, concludes that corneal corpuscles may undergo transitional forms, may act as phagocytes, and are a source of macrophage formation.

The papers reveal the continued interest in clinical pathology and the growing significance of experimental work in American ophthalmology.

Wm. M. James.

PSYCHOLOGICAL OPTICS. By Vernon W. Grant, M.A. With an introduction by Thomas G. Atkinson, M.D. Clothbound: 230 pages, bibliography, index. Published by The Professional Press, Inc., Chicago, Ill., 1938.

"Psychological optics is defined as the study of the mental side of vision." "What we see, depends largely on what we are looking for." "Visual responses are designed to adapt the organism to its environment, which means to serve its wants and preserve it from injury." "Vision, therefore, consists of conscious impressions and muscular adjustments, either voluntary or reflex." These are a few of the leading statements in this book and give a general idea of its content. The chapter headings indicate the wealth of detail covered; for example, fundamentals of behavior, as seen in general psychology and applied to vision; a discussion of the visual reaction system; visual per-

ception; visual perception of space; attention in relation to vision; visual sensations and illusions.

One of the most interesting discussions is that of suppressed vision, which can be interpreted in terms of the psychology of habit formation. Edward Jackson more than hinted at the importance of visual psychology in discussing the problem of aniseikonia.

The book forms a liaison between physiological optics and visual impressions, and should be of concern to all ophthalmologists, particularly those interested in orthoptics, muscle anomalies, and reading difficulties.

It is well illustrated with line drawings accurately explained. However, in the reviewer's opinion, a bad psychologic impression is obtained as a result of the poorly printed small type used throughout.

Derrick Vail.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is only mentioned in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. General methods of diagnosis
2. Therapeutics and operations
3. Physiologic optics, refraction, and color vision
4. Ocular movements
5. Conjunctiva
6. Cornea and sclera
7. Uveal tract, sympathetic disease, and aqueous humor
8. Glaucoma and ocular tension
9. Crystalline lens
10. Retina and vitreous
11. Optic nerve and toxic amblyopias
12. Visual tracts and centers
13. Eyeball and orbit
14. Eyelids and lacrimal apparatus
15. Tumors
16. Injuries
17. Systemic diseases and parasites
18. Hygiene, sociology, education, and history
19. Anatomy, embryology, and comparative ophthalmology

5

CONJUNCTIVA

Ruata, V. Rickettsiosis and trachoma. *Rassegna Ital. d'Ottal.*, 1938, v. 7, Sept.-Oct., pp. 621-648.

The author presents a valuable critical review of our knowledge to date of the etiology of trachoma. He offers the following conclusions: An aqueous emulsion of trachomatous tissue contains a virus capable of reproducing true trachoma in the human conjunctiva. These filtrates often contain granular elements which greatly resemble Prowazek-Halberstaedter bodies and also rickettsia bodies. The inoculation of trachomatous material or the filtrate into the vitreous of rabbits produces a local nodular reaction, devoid of specific character. Inoculation of this material into other structures (testicles, glands) produces a nonspecific inflammatory reaction which cannot be proved due to the trachoma virus. Attempts to prove the existence of rickettsia bodies in trachoma by inoculation of the louse have not given a definite answer, nor have the attempts to cultivate the tra-

choma virus and the rickettsioid bodies by Carrel's method.

Eugene M. Blake.

Shlikova, B. D. The use of perilla oil in the treatment of trachoma. *Viestnik Ophth.*, 1938, v. 13, pt. 5, p. 677.

An analysis of the results of 100 cases, treated with the oil derived from the seeds of *Perilla Acymoides Labiatae*. It is used in topical applications and as drops instead of chaulmoogra oil, which in Russia has to be imported. The result was excellent in 17 percent of the cases, good in 36 percent, and satisfactory in 47 percent. The best results are obtained in early trachoma, with improvement setting in rapidly, and the final scars being thin.

Ray K. Daily.

Tikhonovich, I. F. A case of bilateral tuberculous conjunctivitis palpebral and scleral. *Viestnik Ophth.*, 1938, v. 13, pt. 5, p. 695.

The diagnosis was made by inoculation into a guinea pig, and the case recovered under a nourishing diet, cod-liver oil, ultraviolet irradiation, mer-

cury injections, and silver-nitrate and iodoform salve locally.

Ray K. Daily.

Wilson, R. P. Heterotopic bone in conjunctiva. Giza Mem. Opth. Lab., 1937, 12th ann. rept., p. 50.

A male aged twelve years came to the hospital on account of a small lump under the lid in the region of the outer canthus, gradually increasing to the size of a pea. Just below the palpebral conjunctiva was found a large island of normal compact bone, and also trachoma scar and pathology.

Lawrence G. Dunlap.

Yousefova, F. I., and Bogdanovitch, S. N. Lupus erythematosus of the conjunctiva. Ann. d'Ocul., 1939, v. 176, Jan., pp. 27-32.

A 23-year-old patient with fibroid pulmonary tuberculosis and typical lupus erythematosus of the face also had conjunctival involvement. This consisted of small gray-white granular papules with slightly depressed centers. Biopsy showed invasion of lymphocytes, monocytes, eosinophiles, epithelioid cells, and Langhans giant cells. Tuberculin treatment was abandoned because of marked focal reactions. Some improvement was obtained with mercurials.

John M. McLean.

6

CORNEA AND SCLERA

Awerbach, M. I. A case of corneal transplantation. Viestnik Opht., 1938, v. 13, pt. 5, p. 690.

The author reports corneal transplantation in a case of corneal burn with preoperative vision 0.01 percent. The final visual result, thirteen months after operation, was normal visual acuity.

Ray K. Daily.

Castroviejo, Ramon. Corneal implant. Rev. Oto-Neuro-Oft., 1938, v. 13, Sept., p. 205.

This is a Spanish adaptation of a collective review which appeared in Surgery, Gynecology, and Obstetrics, 1937, v. 65, p. 589. Edward P. Burch.

Edison, S. M. Interstitial keratitis treated with zinc ionization. Illinois Med. Jour., 1938, v. 73, May, p. 405.

The author states that zinc ionization seems to be of benefit in promoting absorption of infiltrates and scars in interstitial keratitis, especially if his method and electrodes are used.

Theodore M. Shapira.

Golubeva, K. Metastatic ocular involvement in influenza pneumonia. Viestnik Opht., 1938, v. 13, pt. 4, p. 543.

In twenty years at the ophthalmic hospital in Tul there were four cases of metastatic episcleral abscess complicating respiratory infections. In three the causative agent was the staphylococcus and in one the pneumococcus of Frankel. In the latter case there were at the same time iritis and neuritis; also the inflammatory symptoms were less acute, the course less stormy, and the final result better than in the cases caused by the staphylococcus.

Ray K. Daily.

Katznelson, A. B. Epibulbar tuberculosis. Viestnik Opht., 1938, v. 13, pt. 4, p. 507.

A review of the literature and a report of three cases of tuberculous keratoconjunctivitis, with the diagnosis verified by animal inoculation. One case presented a large solitary granuloma at the limbus, the second a localized process involving the cornea and adjacent conjunctiva, and the third a diffuse infiltrative process of the cornea and con-

junctiva. The clinical findings and the pathologic pictures of tissues excised for biopsy refute the contention of Junius that true epibulbar tuberculosis occurs only in the form of small nodules, with slow and insignificant necrosis and with a scanty content of bacilli. The authors' conclusion is that epibulbar tuberculosis takes various and transitional forms. It develops as a result of subconjunctival infection and spreads superficially and deeply. Epibulbar tuberculoma is usually associated with severe generalized tuberculosis and is the result of a hematogenous infection. Its prognosis is serious for the eyeball and for life. Its therapy should consist of constitutional stimulation and of the various forms of irradiation. (Photomicrographs.)

Ray K. Daily.

Knapp, A. A. Results of vitamin-D-complex treatment of keratoconus. *Amer. Jour. Ophth.*, 1939, v. 22, March, pp. 289-292.

Kostenko, F. M. Treatment of trachomatous pannus with cadaver mucous membrane, preserved on ice. *Viestnik Ophth.*, 1938, v. 13, pt. 4, p. 500.

For Denig's transplantation Kostenko uses mucous membrane excised from lips of cadavers and preserved on ice from one to six days. In nine cases he found the material suitable, taking readily, and having a favorable effect on old cases of trachoma. It was gradually absorbed and left no cosmetic blemish. The author recommends suturing the transplant to the tendons of the four recti muscles.

Ray K. Daily.

Krachmalnikov, L. K. The etiology of filamentous keratitis. *Viestnik Ophth.*, 1938, v. 13, pt. 4, p. 558.

A report of a case which the author attributes to ovarian hypofunction.

Ray K. Daily.

Medvedev, H. I. Partial keratoplasty. *Viestnik Ophth.*, 1938, v. 13, pt. 6, p. 733.

An analysis of 24 cases. The results are not good in eyes with leucoma, and the author considers the indications for this operation very limited.

Ray K. Daily.

Moretti, Egisto. Contribution to the surgery of trachomatous pannus. *Ann. d'Ocul.*, 1939, v. 176, Jan., pp. 41-52. (See *Amer. Jour. Ophth.*, 1939, v. 22, Feb., p. 221.)

Natanson, M. C. Requirements and indications for keratoplasty. *Viestnik Ophth.*, 1938, v. 13, pt. 4, p. 497.

In the author's opinion the main indication is a corneal leucoma with good projection and normal intraocular tension. Extensive vascularization, adhesion, and synechia make the prognosis unfavorable. The most favorable age is from fourteen to thirty years. Syphilis may cause disagreeable operative complications and should be treated pre-operatively. Patients with as much as 0.1 vision should not be subjected to transplantation.

Ray K. Daily.

Rintelen, F. Protection of the implant in optical keratoplasty. *Ophthalmologica*, 1938, v. 96, Dec., p. 155.

The author anchors the implant by means of two pairs of sutures at right angles to each other, placed in the conjunctiva and traversing the cornea. To protect the corneal tissue, a sheet of gutta percha is laid between it and the sutures. A window in the gutta percha permits observation of the cornea.

F. Herbert Haessler.

Sgrosso, Salvatore. Keratoplasty. *Rassegna Ital. d'Ottal.*, 1938, v. 7, Sept.-Oct., pp. 577-592.

The author reports two cases of keratoplasty, one of which was of the partial, non-perforating type, the other

done by transplanting the clear peripheral portion of the cornea to the center. So far as healing was concerned both cases were successful, but the transparency of the cornea was not maintained satisfactorily in either case.

Eugene M. Blake.

Talkovskii, S. I. Neurologic data on the corneal processes in herpes zoster ophthalmicus. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 636.

A review of the literature and a report of a case with central involvement of the cornea, involvement of the trigeminal and dysfunction of the sympathetic. On this basis the author concludes that herpes zoster ophthalmicus is a tissue reaction to various types of irritant. The seat of disease is usually a portion of the trigeminal. Involvement of the Gasserian ganglion is common but the process may begin in its peripheral branches or associated nerves. The trigeminal, which morphologically and physiologically resembles the posterior nuclei of the cerebrospinal nerves, determines the biologic processes in the ectodermal portion of the cornea, and is neurotropic to the ectodermal viruses. The development of the corneal process, and its form and localization, are determined by the morphology of the neural apparatus of the cornea and the state of the nervous elements anatomically connected with it.

Ray K. Daily.

Wilson, R. P. Bilateral multi-nodular episcleritis (tuberculides). *Giza Mem. Ophth. Lab.*, 12th ann. rept., 1937, pp. 87-88.

A man aged 36 years, was seen with an early bilateral ocular inflammation which progressed until multiple yellowish nodules appeared around the limbus in each eye, especially in the intermar-

ginal area. Although much elevated, these nodules did not ulcerate and were not tender. The corneae remained clear and recovery was complete after two months treatment with tuberculin. There was no recurrence.

Lawrence G. Dunlap.

Wilson, R. P. Leprotic keratitis. *Giza Mem. Ophth. Lab.*, 1937, 12th ann. rept., p. 57.

In the blind right eye of a female aged fifty years, a leper of the advanced nodular type, a fleshy granular tumor covered the cornea and sclera. The cornea of the left eye was nebulous and showed a similar fleshy pannus. Multiple nodules were scattered over the body, especially the face, arms, and hands. Ziehl-Nielsen-stained sections showed enormous numbers of *B. leprae* in all forms, both intracellular and extracellular. The iris and ciliary body also contained a few lepra bacilli. The choroid and retina were free from any sign of inflammatory reaction.

Lawrence G. Dunlap.

7

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Babel, J. Eye manifestations in a patient with the meningotyphus of swineherds. *Ophthalmologica*, 1938, v. 96, Dec., p. 159.

This disease is not uncommon among the swineherds of Switzerland, France, and northern Italy. The patient in question had great lassitude and meningeal as well as abdominal symptoms in the course of a febrile disease. He had had ocular pain since the onset of fever, and on physical examination was found to have a bilateral fibrinous iritis. Cultures and animal inoculations failed to reveal a causative organism.

F. Herbert Haessler.

Bourdier, F., and Stein, M. Traumatic cyst of the iris. *Bull. Soc. d'Ophth. de Paris*, 1937, Dec., p. 731.

A cyst of the iris developed at the site of an anterior synechia of iris with corneal cicatrix, twenty years after perforating injury of the globe. Three c.c. of fluid was aspirated from the cyst, and it reformed in fifteen days. Treatment discussed includes excision of that portion of the iris, aspirating contents and injecting phenol, and partial ablation. Complete removal by iridectomy was impossible because the wall of the cyst was incarcerated in the cicatrix.

Harmon Brunner.

Burnier, Penido. Adie's syndrome. *Rev. de Oft. de São Paulo*, 1938, v. 6, Oct.-Nov.-Dec., pp. 187-194.

A woman of 48 years for three years had pain in the right eye radiating to the neck, and a typical pupillotomy of the same eye. The tendinous reflexes of the lower limbs were absent. Blood and cerebrospinal-fluid tests for syphilis were negative. The biomicroscope showed atrophy of the iris of the affected eye, including pigmentary border of the pupil. The author calls attention to the harm done by confusion of such cases with tabes. Adie's syndrome has nothing to do with syphilis.

W. H. Crisp.

Magitot and Morax. The curative action of retrobulbar injections of alcohol in some cases of gonococcal iritis. *Bull. Soc. d'Ophth. de Paris*, 1937, Oct., pp. 617-620.

Reported in 1936, this procedure was utilized to control pain in intractable cases, and clinical improvement was observed in some. It is suggested that in this type of iritis the symptoms are due less to the number of organisms in the tissues than to the intensity of the

neurovascular reaction. In the discussion, cases were reported of hemorrhagic glaucoma where relief of pain made enucleation unnecessary.

Harmon Brunner.

Michaud, Paul. Horner syndrome provoked by retrobulbar injection of acetylcholine. *Bull. Soc. d'Ophth. de Paris*, 1938, March, p. 138.

A patient of 46 years with thrombosis of the central vein of the retina was given a retrobulbar injection of 50 mg. of acetylcholine, and three days later ten mg. more. After three days more the vision was much improved; but there was a paralysis of the external rectus and superior rectus muscles, and a Horner's syndrome. The paralysis disappeared, but the typical Horner's syndrome persisted.

Harmon Brunner.

Reed, J. R., and Goldfain, E. Recurrent iritis in undulant fever with concurrent rheumatic and/or arthritic disease. *Jour. Oklahoma State Med. Assoc.*, 1938, v. 31, Sept., pp. 302-304.

Five cases of recurrent iritis with concurrent joint disease are reported. All five had a positive skin test and positive opsonic index for brucella, four of the five having also a positive agglutination test. Vaccine treatment produced a localized reaction in one case. The authors conclude that undulant fever was the probable cause in these cases, and that, in the absence of other cause, evidence of chronic brucellosis should be searched for in cases of iritis.

T. E. Sanders.

Reid, A. McKie. A case of congenital aniridia fitted with pigmented contact glasses. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 57, pt. 1, p. 434.

A patient with aniridia which had

greatly handicapped his business and social life was fitted with a contact glass with the corneal portion opaque except for a clear central pupil. The spherical correction was -4.00 at 10 mm. in front of the cornea and gave the patient 6/6 vision.

Beulah Cushman.

Sédan, Jean. Granuloma of the iris appearing before a pulmonary tuberculosis and permitting an earlier diagnosis. *Bull. Soc. d'Opht. de Paris*, 1937, Dec., p. 701.

A large, yellow, gummatous mass appeared on the pupillary border in a twelve-year-old girl. Attention is directed to the unusual site and to the formation so very similar to a gumma. Observations cover two years.

Harmon Brunner.

Teulières, M., and Beauvieux, J. Pearly cyst of the iris following trauma, with inclusion of an eyelash in the anterior chamber. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 400-405. (See *Amer. Jour. Ophth.*, 1939, v. 22, March, p. 350.)

Zabotinskaja, R. P. The effect of paracentesis of the anterior chamber on the course of tuberculous iritis. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 520.

This is the report of a laboratory study on rabbits, to verify Schieck's claims on injection of blood into the anterior chamber in tuberculous iritis. The report, based on a period of observation of six to eight months, shows that this procedure brings about a brief and transitory improvement, which is followed by exacerbation. In addition there is an unfavorable effect on the fellow eye, manifesting itself in the appearance of fresh tubercles.

GLAUCOMA AND OCULAR TENSION

Atchison, H. H. Case of progressive atrophy of the iris and absolute glaucoma. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 430.

A woman 35 years old, who was found to have absolute glaucoma, gave a history of an irregular pupil, first noticed twelve years previously, and which had gradually become larger and drawn nasally. Later posterior precipitates and a keratitis bullosa were found.

Beulah Cushman.

Clarke, S. T. Mecholyl and prostigmine in the treatment of glaucoma. *Amer. Jour. Ophth.*, 1939, v. 22, March, pp. 249-257.

Davies, W. S. Nevus flammeus and arrested hydrophthalmos. *Amer. Jour. Ophth.*, 1939, v. 22, March, p. 298.

Fradkin, M. I. Hemato-ophthalmic barrier in chronic vagotonus and sympathicotony. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 647.

This laboratory investigation on rabbits demonstrates that raised sympathicotonus leads to lowering of the barrier to crystalloids. The permeability remains unchanged in increased vagotonus.

Ray K. Daily.

Kantorovich, A. I. Sclero-iridectomy for glaucoma in the Dniepr Eye Hospital. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 485.

As to 79 operations, vision was improved in 67 percent of the eyes, and in 96.2 percent tension was normalized. From this experience and a review of the literature the author concludes that the procedure is as effective as any other antiglaucomatous operation.

Ray K. Daily.

Nectoux, René. The action of yohimbine on the visual fields of a glaucoma patient. *Bull. Soc. d'Opht. de Paris*, 1938, no. 2, Feb., p. 103.

The field of one eye was constricted to within 15 degrees of fixation. The other field had a nasal step. The patient refused operation. Two mg. yohimbine hydrochloride was given daily for five days. The constricted field became smaller, but the nasal step disappeared in the other eye. The intraocular tension was slightly lowered. The author concludes that yohimbine depends upon the integrity of the local circulatory system for its effectiveness.

Harmon Brunner.

Pletneva, H. A., Raeva, H. V., and Voronina, E. G. Biologic analysis of the aqueous in glaucoma. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 462.

A detailed report of a laboratory investigation which recorded the effect of the aqueous on a frog's heart. The material consisted of 55 glaucomatous eyes, 41 cataractous eyes, and 2 eyes with iridocyclitis. In 40 percent of the glaucomatous eyes the aqueous contained a sympathicotrophic substance, in 28.8 percent a vagotropic substance, and in 12.7 percent both.

Ray K. Daily.

Rozovskaja, S. B. The significance of elastotonometry in the diagnosis of glaucoma. *Viestnik Opht.*, 1938, v. 13, pt. 6, p. 749.

A review of the literature, a detailed report of the author's own investigation on the phenomena of elastotonometry, and a comparison of data obtained by this procedure with the data afforded by the daily tension curve. The conclusions are that the elastotonometric curves show morning and evening variations. In 62.6 percent of glaucoma

cases the evening curve was normal and the morning curve definitely pathologic. In 25.3 percent of glaucoma cases both the evening and morning curves were pathologic. In 12 percent of the cases the evening curves showed greater deviation from normal than the morning curves. In these cases the daily tension curve was of a reverse character. In normal eyes there was no difference between the morning and evening curves. This was true also in cases in which the intraocular tension was normalized by miotics or operation. Of 107 cases, in 103 there was agreement between the elastotonometric and daily tension curves, and only in 4 did the elastotonometric curves show greater deviation in the evening, while the intraocular tension was highest in the morning.

Ray K. Daily.

Schmelzer, H. On the general causes of the origin of primary glaucoma. *Arch. de Oft. de Buenos Aires*, 1938, v. 13, Aug., p. 401.

In an effort to determine basic causes, studies of blood chemistry were made on 55 patients suffering from primary glaucoma and on 45 patients who were free from the disease.

The most significant alteration was a hypercholesterinemia which occurred in 51 of the 55 patients with glaucoma. The author feels that hepatic dysfunction may account for the abnormal cholesterol values in the blood serum, the liver cells having lost their capacity for storing cholesterol and their power of regulating its assimilation.

In addition to orthodox local measures against primary glaucoma, such as miotics, it is suggested that a diet rich in carbohydrates and low in fats and proteins, together with small doses of insulin, may be beneficial.

Edward P. Burch.

Zaverucha, F. M., and Tebenikhina, V. I. The effect of muscular fatigue on intraocular tension. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 489.

A report on a laboratory investigation relative to the effect of muscular fatigue on blood pressure, intraocular tension, and retinal blood pressure of normal athletes and glaucoma patients. In normal persons, the data obtained show no interrelation in these functions. The effect of muscular exercise on intraocular tension was inconstant. In 55 percent of the cases it was lowered, in 47 percent it was raised, and in 10.5 percent it remained unchanged. The effect of exercise on glaucoma patients was also variable, and no prediction as to its effect in an individual case is possible.

CRYSTALLINE LENS

Bonnet, P., and Paufigue, L., *Cataract: the value of total extraction*. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 439-445.

After a study of two hundred such cases, the authors consider that the operation of total extraction is contraindicated in nuclear, intumescent, and hypermature cataracts. In these cases they prefer the Daviel operation. After study of two thousand cases operated upon by the method of total extraction, the authors consider this the method of choice in most cases. Careful slitlamp study is necessary to determine the anatomic classification of the cataract. In senile uncomplicated cataract, total extraction is not followed by vitreous prolapse, detachment of choroid or retina, vitreous opacities, or secondary glaucoma to any greater extent than the Daviel method. Preliminary iridectomy is recommended in cases compli-

cated by synechiae or hypertony, and in some diabetics.

Clarence W. Rainey.

Dejean, C. Three safety measures for facilitating total extraction of cataract. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 436-438.

The danger of vitreous loss prevents the wide-spread use of the method. Certain operative procedures lessen this danger. One is akinesia of the superior-rectus muscle obtained by retrobulbar injection into the inferior face of the muscle, at the junction of the middle and posterior thirds. Hypotony is the rule and the operation is begun about the tenth minute after the injection. Tonometry is used systematically. Where the tension goes up after retrobulbar injection, the operation is deferred four or five days, and the tension is then lowered by another injection. The third procedure is use of a corneoscleral suture. The author also describes his special lens forceps.

Clarence W. Rainey.

Foster, J. Subepithelial disseminated traumatic cataract of Vogt. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 436.

Seven months after an intraocular fragment of steel was removed from the vitreous, there was a dense central cataract with small, discrete, intensely white, subcapsular spots distributed along the lines of the sutures.

Beulah Cushman.

Graves, Basil. Cataract and other operations during deep sleep induced by paraldehyde and omnopon. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 309.

The author feels that in the safety of paraldehyde narcosis (in which the eye

does not roll up) speed is not a factor and cataract extraction may be done deliberately and with great caution. He combines omnopon with the paraldehyde and several days previously he usually tests its effect as to the possibility of causing vomiting. He describes his technique of cataract extraction.

Beulah Cushman.

Lagrange, Henri. Forceps for intracapsular extraction. *Bull. Soc. d'Opht., de Paris*, 1938, no. 1, Jan., p. 22.

Presentation of capsule forceps with concave surface to approximate the curve of the anterior capsule and with a concavity in the jaws. (3 photographs.)

Harmon Brunner.

Lagrange, H., and Goulesque, J. Original technique for total extraction of cataract. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 432-435.

The essential points of the method are a gentle technique for avoiding injury to the zonula and ciliary body, a large corneal incision, and a conjunctival flap or bridge. The authors mention a special capsule forceps.

Clarence W. Rainey.

Porsaa, Kaj. Posterior lenticonus. *Oft. Selskab i Köbenhavn's Forhandlinger*, 1937-1938, pp. 5-7. In *Hospitals-tidende*, 1938, Dec. 13.

This condition was discovered incidentally in a man twenty years old. The right eye was strongly myopic and the vision was limited to hand movements at two feet. The pupillary reflex showed a central dark spot surrounded by a light or dark zone according to the position of the mirror. The slitlamp revealed a symmetrically rounded bulge of the posterior capsule backward into the vitreous, which at the base measured about one fourth of the diameter of the lens. The lens was otherwise free

from opacities and normal in every way. The central part of the lens was more myopic than the periphery. The left eye was hyperopic and had normal vision.

Posterior lenticonus is a very rare disorder, and since it is usually associated with lenticular opacities it is not often demonstrable with the slitlamp.

D. L. Tilderquist.

Pritzker, L. V. The cutaneous reaction to lens albumen. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 673.

Among 78 cases tested, a positive reaction was obtained more frequently in cataract patients than in those with transparent lenses. In 20 percent of postoperative cataract cases, the formerly negative reaction became positive 11 to 17 days after the operation. Patients with traumatic cataracts gave the greatest percentage of positive reactions.

Ray K. Daily.

Saint-Martin. New series of results of total extraction of cataract. The primary importance of preoperative and postoperative care. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 446-459.

The author presents tabular statistics concerning 237 cases of cataract removed by total extraction. A previous report had been made by the author in 1935. The results of the two series have been in agreement.

Clarence W. Rainey.

Sourdille, G. P. Statistics as to intracapsular lens extraction. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 424-431.

The author discusses the results obtained in operating upon 607 cases of senile cataract by the intracapsular method. In uncomplicated cases the vision was better than 8/10 in 87 to 89 percent. The complications were post-

operative hemorrhage, which occurred in the first week in 35 cases, and loss of vitreous, which occurred in 6.7 per cent of the cases.

Clarence W. Rainey.

Tille, H., Pillet, P., and Busnel, R. G. Microincineration and microspectroscopic analysis of the normal and pathologic lens, with special regard to two cases of black cataract. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 407-424.

The authors conclude that in normal lens substance, in white senile cataract, and in amber cataract there is no iron, copper, or zinc in appreciable quantity. Copper was found in black cataractous lens material, especially in the lens nucleus. Iron was found in black cataract, especially in the lens periphery. Hematoporphyrin was not found.

Clarence W. Rainey.

Villard, H. Systematic conjunctival flap in the operation for complicated cataract. *Bull. Soc. Franç. d'Opht.*, 1938, v. 51, pp. 459-462.

In cases where the author thinks that intraocular infection might follow cataract operation, the following procedure is used: An incision is made in the conjunctiva at the limbus, from the 9 to the 3-o'clock position, and upward dissection is done. Two vertical sutures, fastened above and below, serve to draw the flap securely down over the wound, and to cover most of the cornea.

RETINA AND VITREOUS

Ballantyne, A. J., Michaelson, J. C., and Heggie, J. F. Vascular changes in the retina, optic nerve, brain, and kidney: a clinical and pathologic study. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 255.

Ophthalmoscopic observation was followed by histologic examination of pipe-stem sheathing of a central retinal artery, with parallel studies of comparable arteries of the kidney and brain. The vessels showed marked proliferation of the subendothelial cells and multiplication of the elastic fibers, causing irregular thickening of the intima and narrowing of the lumen. The thickened cellular intima undergoes complete disintegration into a fatty debris producing the ophthalmoscopic picture as seen. (Illustrations.)

Beulah Cushman.

Bonnet, M. P. Pigment streaks of retina as sequela after detachment of choroid following intracapsular cataract extraction. *Bull. Soc. d'Opht. de Paris*, 1938, no. 1, Jan., p. 55.

A diabetic patient had a massive detachment of the choroid, starting in the superior temporal quadrant, becoming annular, and reaching almost to the macula. After several days the detachment disappeared. The limits of maximal detachment are marked permanently by a fine, black, broken, and sinuous line.

Bourne, M. C., Campbell, D. R., and Tansley, K. Retinitis pigmentosa in rats. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 234. (See *Amer. Jour. Ophth.*, 1939, v. 22, Jan., p. 94.)

Couadau and Planques. Hypertensive neuroretinitis disappearing under medical treatment, recurring during pregnancy, and with slow recovery following premature delivery. *Bull. Soc. d'Opht. de Paris*, 1938, no. 1, Jan., p. 40.

A patient 35 years of age presented in the left eye papilledema, small plaques of exudate, and peripheral hemorrhages. General measures and

acetylcholine medication were instituted. In two months the fundi were normal. One year later (the patient being seven months pregnant) there was an intense albuminuric retinitis in each eye. Seven months later all evidences of retinitis had disappeared. The case is cited as proof that in such cases findings of albuminuric retinitis are not permanent; and that they may represent nephritic exacerbation.

Harmon Brunner.

Dax, E. C. A melanosome-dispersing substance in the blood and urine of cases with retinitis pigmentosa. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 227.

A substance which will expand the melanophores of the frog is shown to be present in the blood and urine of patients with retinitis pigmentosa. Its chemical properties resemble those of the melanosome-dispersing hormone of the pituitary body. Melanophore expansion in frogs was obtained by injection of blood and urine of twenty patients with retinitis pigmentosa. A similar effect was produced by the urine in pituitary abnormalities or physiologic stress. (Illustrations.)

Elsberg, C. A., and Spotnitz, H. Factors which influence dark adaptation. *Amer. Jour. of Physiology*, 1937, v. 120, Dec., p. 689.

As to the effect of bright light in dark adaptation, time is of greater importance than intensity.

Theodore M. Shapira.

Elsberg, C. A., and Spotnitz, H. The neural components of light and dark adaptation and their significance for the duration of the foveal dark adaptation process. *Bull. Neur. Inst. New York*, 1938, v. 7, Sept., p. 148.

Most of the studies were made with red light. To perceive a dimly illuminated object following light adaptation, a message must be transmitted to the visual centers from the retina. The retinal sensitivity increases comparatively rapidly. A longer period of time is necessary before the energy produced in the photosensitive elements of the retina can be perceived. The time required for foveal dark adaptation is in all probability determined by the comparatively slow response of neural areas to weak stimuli after previous light adaptation.

F. M. Crage.

Jeandelize and Thomas. The influence of adrenalin and hypophyseal extract on the curve of dark adaptation in some cases of retinitis pigmentosa. *Bull. Soc. d'Ophth. de Paris*, 1937, Oct., pp. 608-612.

In such cases the visual threshold is above that of normal eyes. It was found that hypophyseal extract raised and adrenalin lowered the threshold. Drugs were administered by injection.

Law, F. W. A contribution to the pathology of angioid streaks. *Trans. Ophth. Soc. United Kingdom*, 1938, v. 58, pt. 1, p. 191.

A review of the different theories of the etiology of angioid streaks is given, with histologic description of a case in which the author showed pictures of the fundi. There was a history of injury to the right eye and an acute gastric ulcer with profuse hemorrhage to which the patient succumbed. Pathologic examination showed folds in the retina, with no breaks in Bruch's membrane.

Beulah Cushman.

Linksz, A., and Raskó, J. Examinations with the Kukan ophthalmody-

namometer. *Therapia* (Hungarian), 1938, v. 15, June, p. 126.

By means of negative pressure the eyeball is held fast and pressed against the rim of a suction cup of 13-mm. diameter. Thus the intraocular pressure is raised, and the appearance and collapse of the arterial and venous pressure are observed with the ophthalmoscope. The eye having an autochthonous regulatory mechanism, the intraocular pressure is in great degree independent of the general blood pressure. The authors found great variations from the ideal rule that the diastolic pressure in the brachial is twice as high as the retinal diastolic pressure. Further they established the following connections: If the intraocular pressure rose above 25 mm. Hg the retinal diastolic pressure was always found to be higher than 40 mm. Hg, and if the retinal diastolic pressure was greater than 65 mm. Hg the ocular tension was higher than 24 mm. Hg. Similarly, if the intraocular pressure was less than 13 mm. Hg the retinal diastolic pressure was never higher than 40 mm. Hg. While in one man the diastolic pressure of the brachial was 65 mm. Hg, the retinal diastolic pressure differed in the two eyes, being 40 and 60 mm. Hg respectively, while the intraocular tension of the two eyes correspondingly was 16 and 25 mm. Hg. R. Grunfeld.

Michaud, Paul. The oculocardiac reflex observed after a retinal-detachment operation. *Bull. Soc. d'Opht. de Paris*, 1938, March, p. 136.

Thirty-six hours postoperatively the patient had an attack of vomiting and pulse was reduced to 40. The bradycardia was relieved by atropine. The site of operation was in the superior nasal quadrant of the right eye. It is presumed the ciliary nerves were dam-

aged, causing a central vagus stimulation. Harmon Brunner.

Nagy, Ferenc. Vasodilator substances in diseases of the eyeground. *Magyar Orv. Arch.* (Hungarian), 1938, v. 39, p. 643.

The author describes four cases in which he obtained some improvement in visual acuity by amyl-nitrite inhalation or acetylcholin injection. The treatment is indicated in albuminuric retinitis, choroiditis, atrophy of the optic nerve, retinitis pigmentosa, and so on. Although the vasodilators frequently fail to fulfil the expectations based upon them, the few instances in which they improve vision and increase the visual field make it desirable to try their application in every case indicated. R. Grunfeld.

Offret, G. Bilateral venous retinal lesions in a young girl, preceding by two months the appearance of recurrent vitreous hemorrhages. *Bull. Soc. d'Opht. de Paris*, 1937, Oct., pp. 578-587.

This patient had a vasomotor instability more evident in the extremities. Complete physical studies and tests revealed only a prolonged blood-clotting time. The fundi showed venous tortuosities, thrombi, flame-shaped retinal hemorrhages, and frequent areas of periphlebitis. These became more marked distally. No immediate cause of the vitreous hemorrhages was found in spite of hospitalization. Etiology is discussed. (2 plates, 6 references.)

Strachov, V. P. Intracapsular cataract extraction. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 454. (See *Amer. Jour. Ophth.*, 1939, v. 22, Feb., p. 230.)

Vilenkina, A. I. The fundus in the diagnosis, prognosis, and course of hypertension. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 470.

A tabulated report of examination of 28 patients with hypertension relative to blood chemistry, blood pressure, retinal pressure, and fundus changes. The author shows that the ocular findings are indicative of the phase, character, and course of hypertension. He therefore urges close coöperation between internist and ophthalmologist. He suggests the term "hypertensive fundus" for the early stages of essential hypertension, and "arteriosclerotic retinopathy" for its late stages. "Angiospastic retinitis," indicative of malignant hypertension, should be replaced by the term "ischemic retinopathy."

Ray K. Daily.

Wilson, R. P. Neuroretinitis (probably bilharzial in origin). *Giza Mem. Ophth. Lab.*, 1937, 12th ann. rept., pp. 88-89.

This is the second case in recorded medical literature of neuroretinitis of bilharzial origin. The first case was reported in 1924. Both patients were young males, aged respectively 25 and 21 years. In each case the left eye was affected and the fundus lesions consisted of several rounded white or yellowish-white spots near the temporal side of the disc or in relation to the temporal vessels. In both cases the size of the spots was the same (about 1/3 d. d.) and small macular hemorrhages were present. Both cases cleared up under antimony tartrate injections.

King, J. E. J. Oxycephaly. A new operation and its results. *Arch. Neur. and Psychiatry*, 1938, v. 40, Dec., p. 1205.

In oxycephaly, a premature closure of the skull sutures prevents normal expansion of the brain in its growth. Ocular results of this condition include exophthalmos, papilledema, and later optic atrophy. The author reports the case of an eight-year-old boy operated on in two stages, first on one side of the skull, and ten weeks later on the other side. The operative procedure consisted

in making a number of burr holes through the skull about 5 cm. apart, and connecting these holes by linear cuts through the bone. The result was a mosaic of skull fragments resting on the dura, allowing the brain to expand by further separation of the fragments. Subjective and objective improvement of the patient were noted. (Illustrations.)

McAlpine, Douglas, Familial neuromyelitis optica: its occurrence in identical twins. *Brain*, 1938, v. 61, Dec., p. 430.

The clinical and pathological features of neuromyelitis optica as it occurred in identical twins are described. It is concluded that it is a distinct member of the demyelinating group of diseases.

T. E. Sanders.

Skydsgaard, H. Intermittent choked discs in intracranial tumors. *Oft. Selskab i Köbenhavn's Forhandlinger*, 1937-1938, pp. 25-32. In *Hospitalstidende*, 1938, Dec. 13.

Two cases of intracranial tumor are cited in which over a period of five years or more there appeared recurring attacks of increase in intracranial pressure with marked choked disc, followed by improvement in symptoms and disappearance of the papilledema. In one instance a tumor was found in the right frontal lobe and the periodic attacks had undoubtedly been caused by intermittent hemorrhage from the tumor. In the other case, the tumor was located at the base of the brain near the tentorial incisure, and caused direct pressure and blocking of the ventricles, especially the third. Since the tumor was partly cystic the periodicity of the pressure might be explained by intermittent emptying and refilling of the cysts.

D. L. Tilderquist.

Watkins, A. L. The cerebrospinal fluid in optic neuritis, "toxic amblyopia," and tumors producing central scotomas. *New England Jour. Med.*, 1938, v. 220, Feb. 9, pp. 227-231.

The cerebrospinal-fluid findings in 120 cases of acute and chronic retrobulbar neuritis, "toxic amblyopia," and tumors producing central scotomas are reported. In acute retrobulbar neuritis without demonstrable cause the spinal fluid was normal except in older cases associated with known multiple sclerosis (25 to 50 percent). In these there were a few lymphocytes, a high normal protein and a strong first-zone gold-sol reaction. The spinal fluid was normal in so-called chronic retrobulbar neuritis, and in 95 percent of the cases of probable "toxic amblyopia." In all patients with tumor or aneurysm producing central scotoma, the spinal-fluid protein was increased two to five times. This proved to be a valuable differential point.

Guillermín, M., and Pesme, J. Pneumococcic arachnoiditis of the optic chiasm. *Bull. Soc. d'Opht. de Paris*, 1938, no. 1, Jan., p. 16.

The report relates to a patient complaining of abrupt diminution of vision to O.D. 0.01, O.S. 0.2, and having bilateral papilledema, contracted fields, and a quadrant field defect. All laboratory tests and examinations were negative. The symptoms progressed. In the search for infection, the optic chiasm was exposed and was found to be covered with a greatly congested arachnoid. The optico-chiasmal cistern was greatly distended with cloudy fluid. The spinal fluid was consistently negative. Later general meningitis developed. Necropsy showed the optic chiasm to be the site of primary infection. Routes of infection are discussed. The authors present the case in the belief that many light cases are overlooked and undiagnosed, and also to refute doubt of the existence of the arachnoid in this area.

Harmon Brunner.

EYEBALL AND ORBIT

Benedict, W. L. Problems in the diagnosis of abscess and tumor of the

orbit. *Amer. Jour. Ophth.*, 1939, v. 22, March, pp. 292-297; also *Trans. Pacific Coast Oto-Ophth. Soc.*, 1938, 26th mtg.

Berz, A. L. An atypical case of true posterior staphyloma. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 545.

A report of a case in a high myope 39 years old. The optic disc was not included in the staphyloma, and the ectatic area was darker in color than the rest of the fundus. The author regards this phenomenon as an anomaly in development; he cites the presence of a misplaced lacrimal punctum in the same eye as supporting this contention.

Ray K. Daily.

Bonnet and Paufigue. Unilateral exophthalmos related to a large cystic tumor of the greater wing of the sphenoid. *Bull. Soc. d'Opht. de Paris*, 1938, March, p. 173.

A male of 57 years had exophthalmos progressive since 1917. There was a large cyst in the greater wing of the sphenoid, and since 1921 the contents of the cyst had been drained by puncture several times a year. Cystic formation of the sphenoid crowding into the orbit could be palpated laterally. There was no pain. The type of cyst was not known. Discussion brought out two more cases of similar nature. One died of another cause. One had become stationary for several years.

Harmon Brunner.

Dragoiu, I., and Crisan, C. Correlation between the development of the crystalline lens and that of the optic vesicle, in relation to an ocular anomaly. *Bull. de l'Acad. de Méd. de Roumanie*, 1938, v. 5, no. 3, pp. 305-308.

In examining serial frontal sections of the head of a frog tadpole which to the naked eye showed left anophthal-

mia, there was found in the left orbit an oval formation surrounded by abundant mesenchymatous tissue. Detailed study showed that the primary optic vesicle had been prematurely separated from the cerebral vessels, probably by mechanical rupture of the optic pedicle. There was no trace of vitreous, cornea, crystalline lens, or iris; but well-developed oculomotor muscles were found inserted into the primitive sclera.

Lamb, H. D. The retina in septic and chronic endophthalmitis of ectogenous origin. *Amer. Jour. Ophth.*, 1939, v. 22, March, pp. 258-266.

Magitot. Subconjunctival injection of adrenalin, and exophthalmos in man. *Bull. Soc. d'Opht. de Paris*, 1937, Dec., p. 721.

The injection was made to secure mydriasis in a case of uveitis. In ten minutes retraction of the upper lid and mild exophthalmos developed. When yohimbine was injected before the adrenalin this did not occur. Though the experience is common in animals, the author finds no previous recorded instance in man. He attributes it to action upon the sympathetics.

Harmon Brunner.

Marine, David. Studies on the pathological physiology of the exophthalmos of Graves' disease. *Annals of Internal Med.*, 1938, v. 12, Oct., p. 443.

Important factors in production and maintenance of exophthalmos are increased anterior pituitary activity, relative or absolute thyroid insufficiency, and increased functional activity of the interstitial cells of the gonads. The exophthalmos following thyroidectomy in rabbits can be cured by the administration of thyroxin or by gonadectomy.

Other factors may be the functional activity of the adrenal cortex and Ca and P metabolism. (Illustrations.)

George A. Filmer.

Naffziger, H. C. Progressive exophthalmos associated with disorders of the thyroid gland. *Annals of Surg.*, 1938, v. 108, Oct., p. 529.

Naffziger considers the status of three patients who have progressive exophthalmos associated with disorders of the thyroid gland and in whom the exophthalmos has progressed to the point where not only the vision but the lives of the patients are threatened.

Theodore M. Shapira.

Nikhinson, A. G. The orbital complications of sinusitis in childhood. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 530.

A report of two cases of orbital phlegmon complicating nasal sinusitis. In both, the orbits were drained externally and the sinuses intranasally. The final result was recovery, with loss of vision in one case. Ray K. Daily.

Polonskii, S. P. Recurrent exophthalmos and choked disc caused by Quincke's edema. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 669.

The patient came from a family with cardiovascular disturbances, and from childhood was subject to attacks of migraine and urticaria. When she was 28 years old the attacks of urticaria were followed by exophthalmos, reduced visual acuity, and choked disc in the left eye. For the first three years the eye returned to normal between the attacks. After that there remained between the attacks some exophthalmos, slight choking of the disc, and some reduction of visual acuity. The history and course of the disease led the author to conclude that this was a case of Quincke's edema.

Ray K. Daily.

Rameev, P. C. Orbital cellulitis in erysipelas of the face. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 667.

A report of a case with recovery under conservative treatment.

Wald, G., Jeghers, H., and Armino, J. An experiment in human dietary night-blindness. *Amer. Jour. of Physiology*, 1938, v. 123, Sept. 1, p. 732.

The dark adaptation of a human subject was measured at regular intervals during a long control period, and during a subsequent period on a diet containing only 50 to 200 U. S. P. units daily of vitamin A, but otherwise complete. A first effect of the deficiency diet was noted within 24 hours. Within 25 days, the threshold of the dark-adapted rods had risen about fifty times that of the dark-adapted cones, which had risen fourfold. Following temporary cure of the initial night-blindness with a single dose of vitamin A, hemeralopia reappeared with greatly increased rapidity. The development of hemeralopia was repeatedly checked temporarily by oral administration of vitamin A or carotene. After intramuscular injection of colloidal carotene the hemeralopia threshold improved to within seven minutes.

Theodore M. Shapira.

Wilson, R. P. Coloboma of the upper lid with microphthalmos and dermoid of cornea. Giza Mem. Ophth. Lab., 1937, 12th ann. rept. pp. 82-85.

A female infant, aged 27 days, had a soft mass about 1 cm. in diameter in the anterior part of the right orbit, protruding through a wide coloboma in the nasal half of the upper lid. The coloboma involved about one half of the ciliary margin and portions of the normal lid lay free on each side of the protruding mass. The tumor extended backward into the orbit and the conjunctiva had a bluish tinge suggestive of underlying sclera. Eight months later the condition having remained stationary, the tumor was excised. On the back of the tumor was a small pigmented cyst (microphthalmic eye) the size of a small pea, and with tough walls. The tumor mass replaced the cornea, anterior chamber, and iris, and there was no trace of lens. The posterior portion of the specimen showed a narrow cavity lined by retinal pigment epithelium.

Lawrence G. Dunlap.

Wilson, R. P. Streptothricial granuloma of orbit. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 70.

A female aged fifteen years, with swelling and drooping of the left upper eyelid for about three months, had a firm hard tumor extending along the whole of the superior orbital margin and deep into the orbit, attached to the periosteum but not to the skin. A piece removed for diagnostic examination showed mycelial filaments, polymorphonuclears, plasma cells, lymphocytes, macrophages, giant cells, and newly formed capillaries, typical of the nodules of actinomycosis.

Lawrence G. Dunlap.

14

EYELIDS AND LACRIMAL APPARATUS

Csillag, Franz. Primary chancre of the eyelid. Orvosi Hetilap (Hungarian), 1939, v. 83, Jan. 7, p. 11.

A portion of the lower eyelid near the inner canthus became swollen and subsequently thickened and hard. A yellowish crust formed upon the surface and later the upper eyelid showed a similar change. No ulceration was noted. Although the epithelium became desquamated the denuded surface was not moist. The tear duct was not permeable. Close to the duct a hard nodule was palpable. The preauricular gland was enlarged. The Wassermann reaction was strongly positive. Since upon institution of antisypilitic treatment a rapid cure set in, the condition was diagnosed as primary syphilitic ulcer.

R. Grunfeld.

Desvignes, Pierre. Syphilis of the lacrimal duct simulating acute dacryocystitis. Bull. Soc. d'Ophth. de Paris, 1938, no. 1, Jan., p. 13.

The author says that a review of literature shows only twelve cases of acute syphilitic infection of the sac. A female aged 36 years had all the signs of an acute infection. Diagnosis was suggested by a nasal ulcer; and was confirmed serologically and therapeutically.

Harmon Brunner.

Morgan, O. G. Observation on the treatment of epiphora, with special reference to some cases treated by dacryocystorhinostomy. Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 163.

A review of the different methods of treatment of congenital occlusion of the lacrimal duct is given, with details of operative interference according to the

Dupuy-Dutemps modification of Toti's method. This technique was used satisfactorily in children, and in adults where probing had failed.

Beulah Cushman.

Offret, A., and Offret, G. **Operative attempt in a case of Marcus-Gunn phenomenon.** Bull. Soc. d'Ophth. de Paris, 1938, no. 2, Feb., p. 61.

The patient had an associated ptosis when the eye was at rest, and a tremor of the upper lid when the jaw was moved to the opposite side. A longitudinal strip of tarsus was sutured to the insertion of the superior rectus. The ptosis was relieved and the jaw winking stopped. (9 references.)

Harmon Brunner.

Palin, Anthony. **Abnormal angulation of palpebral fissures.** Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 457.

A plastic operation is described for repair of the palpebral fissure, which angulated down 15°. A long triangular flap of skin and orbicularis muscle base outward was transplanted from the upper lid to the lower to raise the canthus.

Beulah Cushman.

Paradoksov, L. F. **Surgical treatment of cicatricial entropion of the lower lid.** Viestnik Ophth., 1938, v. 13, pt. 4, p. 550.

The author's procedure consists in excision of a strip of skin over the tarsus, splitting the tarsus, and suturing in such a manner that the upper segment of the tarsus with its overlying conjunctiva is turned on its axis and becomes displaced upward and forward.

Ray K. Daily.

Saint-Martin, R. de. **A modification of the Motais technique for the correction of ptosis.** Bull. Soc. d'Ophth. de Paris, 1938, no. 2, Feb., p. 100. (See

Amer. Jour. Ophth., 1938, v. 21, Dec., p. 1433.)

Shershevskaja, O. I. **Congenital coloboma of the lids.** Viestnik Ophth., 1938, v. 13, pt. 6, p. 822.

A report of two cases. In one the colobomata represented the only abnormality. In the second case there were cicatrices on the skin of the lids, and shortening of the bridge of the nose and of the alveolar process of the superior maxilla. In this case the author attributes the anomaly to amniotic adhesions. The pathogenesis of the first case is not clear.

Ray K. Daily.

Valière-Vialeix. **A case of enormous distention of the lacrimal sac.** Bull. Soc. d'Ophth. de Paris, 1937, Dec., p. 696.

Dilatation resulted from chronic dacryocystitis. The sac held 30 c.c. of fluid. It is the second largest reported.

Harmon Brunner.

Venco, Luigi. **The technique of dacryocystorhinostomy by the external route.** Rassegna. Ital. d'Ottal., 1938, v. 7, Sept.-Oct., pp. 593-612.

In an experience with 200 cases of dacryocystorhinostomy, Venco has found certain procedures of value. He administers a blood coagulant in advance and gives a sedative before the operation. Novocaine infiltration is done externally and a pledget of 5-percent cocaine with adrenalin is placed in the nose. The incision is slightly longer than that for removal of the sac. After the skin incision is made a diathermy bistoury is used for deep dissection.

The author discusses various measures for checking hemorrhage. The sac is freed from surrounding tissues, except at the canaliculi and the dome, and a colored fluid is injected into the sac to aid identification. Bone removal

is done with an 8-mm. electrically driven trephine. The sac and nasal mucous membrane are united by 000 catgut or silk, and when suturing is impossible a rubber tube is tied in place.

Eugene M. Blake.

Wilson, R. P. Elephantiasis lymphangioides of the eyelids, Giza Mem. Ophth. Lab., 1937, 12th ann. rept., pp. 85-86.

A female, aged sixteen years, was treated with a red-hot cautery for a boil on the lower border of the right jaw, over the external maxillary vessels. A dense scar over the angle of the jaw was followed by swelling of the face and thickening and ptosis of the right upper eyelid. Tarsectomy was performed to reduce the thickness and weight of the lid, and microscopic examination of the excised tissue showed greatly dilated lymphatics and filling of the subcutaneous tissues with myxomatoid material.

Lawrence G. Dunlap.

Wilson, R. P. Retention cyst of accessory lacrimal gland (dacryops). Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 59.

A female aged 25 years had in the vicinity of the right lacrimal gland a swelling of the right upper eyelid of ten days duration. It appeared to be cystic, lobulated, and freely movable, and of the size of a large chestnut. It was removed. The pathologic diagnosis was retention cyst of the accessory lacrimal gland, secondary to ascending inflammation.

TUMORS

Doherty, W. B. Melanosarcoma of the iris. Amer. Jour. Ophth., 1939, v. 22, March, pp. 239-249.

Lane, L. A. Occupation in relation to cancer of the eye and adnexa. Amer. Jour. Ophth., 1939, v. 22, March, pp. 267-273.

Meighan, S. and Michaelson, J. C. A case of glioma retinae with special reference to the mode of spread. Trans. Ophth. Soc. United Kingdom, 1938, v. 58, pt. 1, p. 208.

The authors give the clinical and pathological findings in a 3½-year-old child with bilateral retinal glioma. The involvement of the right eye extended to the optic disc, choroid, and anterior part of the nerve. The progress backward in the nerve was interrupted for 1 mm. Its reappearance in the nerve continued for 0.60 mm. and was associated with partial necrosis of nerve fibers and implantation of small secondary nodules in the subarachnoid space. The authors conclude that this examination exemplifies the fallacy of basing operative procedure on the condition of the cut end of the optic nerve, and they advise consideration of exenteration of the orbit if the choroid is found to be involved.

Beulah Cushman.

Montpellier, J., Toulant, P., Foissini, J. Ganglio-neuro-schwanno-spongioblastoma of the orbit. Ann. d'Ocul., 1939, v. 176, Jan., pp. 18-27.

An eight-year-old Arab boy had proptosis of the left eye of two-months duration without other symptoms. An adherent solid tumor was removed from the orbit. Deep X-ray therapy was given for two months. Seven months after the first operation the tumor had

recurred with marked proptosis, loss of vision, and corneal erosion. Exenteration of the orbit was followed by further radiation.

Histologic examination of the first specimen showed a malignant ganglioneuroma. The second specimen was a classical spongioblastoma.

The literature on neurogenic tumors of the orbit is discussed, and the possibility of two separate tumors is dismissed in favor of one complex ganglio-neuro-schwanno-spongioblastoma. (Bibliography.) John M. McLean.

Wilson, R. P. Adenocarcinoma of meibomian gland. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 45.

A female aged 45 years had noted a growing tumor of the left upper eyelid for the previous two years. Two operations had been unsuccessful. After removal the histopathologic appearances suggested that the growth had arisen from a sebaceous (meibomian) gland. Lawrence G. Dunlap.

Wilson, R. P. Capillary angioma secondary to xeroderma pigmentosum. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 47.

A female aged nine years had begun to develop signs of xeroderma pigmentosum when only one year old. This progressed until pigmented areas and atrophic patches were scattered over the whole body. A red sessile tumor the size of a small bean, attached to the ciliary border of the intermarginal strip of the left upper eyelid, was removed. Photophobia was due to diffuse trachomatous keratitis. Tumor sections showed a typical capillary angioma, with no evidence of malignancy.

Lawrence G. Dunlap.

Wilson, R. P. Cavernous hemangioma of bulbar conjunctiva. Giza Mem. Ophth. Lab., 1937, 12th ann. rept. p. 52.

A male aged 35 years had noted for five years a small red mass on his right eye, 3 mm. in diameter and lying midway between the caruncle and the nasal limbus. It was movable with the conjunctiva. Trachoma accompanied the condition. Pathologic examination revealed the type of tumor.

Lawrence G. Dunlap.

Wilson, R. P. Fibroma of eyelid. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 39.

A female aged 45 years had noted for two years a small hard lump in the lower left eyelid gradually increasing in size, painless, nonadherent to skin but adherent to the lower orbital margin, and causing a mechanical obstruction to vision. Pathologic sections showed the typical appearances of a soft fibroma. Lawrence G. Dunlap.

Wilson, R. P. Lipoma of bulbar conjunctiva. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 53.

A female aged eleven years had a soft yellowish rounded tumor, 4 by 4 by 3 mm., midway between the outer canthus and the temporal margin of the limbus, freely movable. It was found to be a lipoma of the bulbar conjunctiva. Lawrence G. Dunlap.

Wilson, R. P. Malignant melanoma of eyelid. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 42.

A female aged 27 years had noted three months previously a lump the size of a pea in her left upper eyelid. When examined she was found to have a large firm tumor of the middle third of the lid, about the size of a walnut,

not attached to the overlying skin, round, apparently cystic, and causing mechanical ptosis. There were enlarged glands in the parotid region and also in the neck. The tumor was found to be a typically malignant melanoma with secondary metastases to the glands.

Lawrence G. Dunlap.

Wilson, R. P. Mixed tumor of lacrimal gland. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 61.

Three cases were seen during the year. One, in a female aged 35 years, was of the "mixed salivary gland" type. One of six months duration, in a female aged 25 years, caused the eye to be displaced markedly downward and forward and restricted the eye movements. The third, in a female aged forty years, was of five years duration.

Lawrence G. Dunlap.

Wilson, R. P. Neurofibroma of the eyelid. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 40.

A female aged sixteen years, with a swelling over her left eye since birth, gradually enlarging, and with marked ptosis of the left upper lid, was found to have a typical neurofibroma.

Lawrence G. Dunlap.

Wilson, R. P. Pigmented tumor of the optic-disc margin (melanoma). Giza Mem. Ophth. Lab., 1937, 12th ann. rept., pp. 92-94.

A female aged 35 years complained of defective vision for the previous ten days, and was found to have a right optic disc almost completely obscured by a dense black globular mass about twice the diameter of the left disc. The first diagnosis was melanotic sarcoma, but when the patient refused operation and was examined a year later, the tu-

mor had not altered either in size or appearance. There was no detached retina and vision was 2/60. The diagnosis was changed to benign melanoma.

Lawrence G. Dunlap.

Wilson, R. P. Reticulum-cell sarcoma of lacrimal-sac region. Giza Mem. Ophth. Lab., 1937, 12 ann. rept., p. 66.

A female aged 36 years, with a lump at the inner canthus of her left eye for the past three months, was thought to have a mucocele of the lacrimal sac, but at operation was found to have a solid tumor occupying the region of the sac. It was removed, but six weeks later there was a mass the size of a walnut at the site of the previous operation, with no glandular involvement. This was removed, and a month later the tumor had recurred, causing proptosis. Ten X-ray treatments were given, the swelling diminished, and six months later the patient was completely cured, but the optic disc was atrophic and vision nil.

A second similar case occurred in a male aged twelve years, in whom a lump had been noted in the region of the left lacrimal sac for the past six months. The tumor was fixed to the deeper tissues but not to the overlying skin. There was no glandular enlargement anywhere. The tumor was found to arise in the wall of the lacrimal sac. The patient could not be followed after removal of the tumor.

Lawrence G. Dunlap.

Wilson, R. P. Sarcoma of limbus. Giza Mem. Ophth. Lab., 1937, 12th ann. rept., p. 55.

A male aged fifty years had noted, two months previously, a small pale fleshy mass of the left eye at the limbal margin. It developed into a large fun-

gating tumor, covering the cornea and encroaching on the sclera, mushroom-shaped, about 1 cm. thick, and firmly attached by a broad base to the cornea and the nasal corneoscleral margin. It was friable and bled easily. Specimens were removed and the eye was afterward enucleated. The tumor was a myxosarcoma. Lawrence G. Dunlap.

16

INJURIES

Anguis, Tullio. Ocular lesions from the juice of euphorbia (spurge). *Rassegna Ital. d'Ottal.*, 1938, v. 7, Sept.-Oct., pp. 649-660.

Euphorbia is an annual plant which blossoms in spring and summer, and occurs frequently in the Mediterranean basin. There are many varieties and they are known to the farmers as the "bad weeds." The juice and seeds of these plants are irritating, vesicant, purgative, and emetic. Thus they have many therapeutic uses. They have been reported to cause conjunctivitis, keratitis, and iridocyclitis. The author reports his experiments with fifteen rabbits, instilling the juice into the conjunctival sac. This regularly produced a conjunctivitis with increase of eosinophiles in the secretion, but no other lesions. Eugene M. Blake.

Block, H. M. Ocular birth injuries of the new-born. *Texas State Jour. of Med.*, 1938, v. 34, May, p. 43.

Block lists and discusses many ocular birth injuries of the new-born.

Theodore M. Shapira.

Bogdonovich, I. I. Changes in the blind spot of the uninjured eye in ocular traumatism. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 534.

The conclusion of the study is that

in perforating ocular injuries and in intraocular foreign bodies the reflex changes in the uninjured eye do not include enlargement of the blind spot.

Ray K. Daily.

Bonnet and Bonamour. "Chrysiasis": impregnation of the cornea by gold salts. *Bull. Soc. d'Opht. de Paris*, 1937, Dec., p. 751.

Three more cases of deposition of gold in the cornea. Each had received gold-salt injections for pulmonary tuberculosis. Small granular deposits were noted in the corneal parenchyma immediately anterior to Descemet's. One case showed deposition in all layers. On account of the occurrence of a conjunctivitis in all cases, with limbal edema, and, in one case, outlining of a meshwork at the limbus by granules, the authors believe the lymphatics carry the gold granules into the cornea. Examination of patients receiving this treatment showed no deposition in those receiving less than three grams of the salt. Harmon Brunner.

Bonnet and Chauvire. Circular rupture of the choroid from contusion of the globe. *Bull. Soc. d'Opht. de Paris*, 1937, Dec., p. 749.

Observations on a patient seen nine days after an automobile accident. A circular vitreous opacity of a diameter greater than that of the lens was observed posterior to the lens. The edges were somewhat thicker, and were festooned and fringed with pigment. Through this diaphanous opacity, pigment granules were seen on the disc and retina, with the typical findings of commotio retinae. It is believed the hyaloid had been torn loose from its ciliary attachments. Similar findings had been observed in traumatic cases; the circu-

lar opacity usually disappearing on or about the ninth day.

Harmon Brunner.

Brodskii, B. S. **Ammonia burns of the eye and their treatment.** *Viestnik Ophth.*, 1938, v. 13, pt. 4, p. 565.

A laboratory study on rabbits. On its basis the author advises early intravenous administration of hypertonic salt solution in addition to local treatment in mild cases, or a Denig transplantation in severe cases.

Ray K. Daily.

Bujadoux, M. **Marking the anterior pole with lipiodol in ocular roentgenography.** *Bull. Soc. d'Ophth. de Paris*, 1938, March, pp. 179-180.

By means of injection of lipiodol at the 12 and 6 o'clock positions at the limbus, foreign bodies may be accurately localized without other apparatus. The author emphasizes that thick lipiodol must be used, or it will spread. (Case report and X rays.)

Harmon Brunner.

Carter, T. J. **Electric welding, particularly eye hazards and protective measures.** *U. S. Naval Med. Bull.*, 1939, v. 37, Jan., pp. 138-142.

Besides burns, electric shock, and inhalation of gases and dusts, the most important hazard of electric welding is injury to the ocular media and retina by the absorption of radiant energy. The rays emitted by the electric welding process include most of the ultraviolet, all of the visible rays, and most of the infrared rays. The conjunctiva and cornea absorb most of the ultraviolet, which gives rise to a severe conjunctivitis and keratitis. The chief cause of injury to the lens is the infrared, the heat of which may cause cataract. Visible light penetrates to the retina and

may cause permanent retinal injury as in eclipse blindness. Adequate eye protection should be given in all occupations subject to such radiation. The use of green or black goggles is suggested.

T. E. Sanders.

Freedman, S. V. **The technique of intraocular foreign-body extraction with the magnet-solenoid.** *Viestnik Ophth.*, 1938, v. 12, pt. 4, p. 503.

This type of magnet permits of the simultaneous use of two magnetic applicators. This combination proved of advantage in extracting a foreign body entangled in the iris. By holding one magnet against the center of the cornea and the other in the wound at the limbus, the serrated foreign body was liberated from the iris and extracted. (Illustrations.)

Ray K. Daily.

Genet. **Mustard gas, conjunctival ischemia, delayed corneal ulcer.** *Bull. Soc. d'Ophth. de Paris*, 1937, July p. 409.

War injury by the gas occurred in 1918, and corneal ulceration in 1931 and 1937. White ischemic areas on the congested conjunctiva were considered as gas burns. The case aroused medico-legal interest.

Harmon Brunner.

Lancaster, W. B. **The technique of extraction of intraocular foreign bodies.** *Amer. Jour. Surg.*, 1938, v. 42, Oct., pp. 14-24.

This excellent article should be read by everyone doing industrial work. The newer methods of making the incision with the diathermy knife to prevent hemorrhage, and the use of diathermy needles around the incision to prevent retinal detachment, are discussed. (4 references.)

Ralph W. Danielson.

Magitot and Dubois-Poulsen. **Localization of intraocular foreign bodies by**

scleral illumination. *Bull. Soc. d'Opht. de Paris*, 1937, Oct., pp. 621-626.

If the media permit, the quadrant containing the foreign body is determined. The scleral lamp is then passed beneath the conjunctiva, and the spot coinciding with the foreign body is marked. Incision is made at this point. The authors claim that trauma is avoided by the procedure.

Harmon Brunner.

Makarov, H. H. Several cases of central retinitis caused by looking at a solar eclipse. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 692.

A report of four cases. In one case the injury resulted from one rapid glance at the sun; and in another it occurred in spite of the fact that the patient was wearing blue glasses. The latent period in such cases is much shorter than in cases of electric ophthalmia caused by exposure to the arc light; the scotoma in the visual field appearing after 10 to 15 minutes, while electric ophthalmia develops 6 to 8 hours after exposure.

Ray K. Daily.

Malbran, Jorge. Traumatic lesions of the iris; partial disappearance of the iris; total disappearance (irideremia). *Arch. de Oft. de Buenos Aires*, 1938, v. 13, Aug., p. 431.

The author reports two cases of disappearance of the iris following trauma. In neither case was there a rupture of the globe. In the first case the disappearance, which followed a dynamite explosion, was partial, while in the second case, after a violent contusion of the globe, there was complete disappearance of the iris and lens. The author speculates upon the manner in which this phenomenon may arise and gives a summary of the literature.

Edward P. Burch.

Merkulov, K. I. Ocular changes in cranial injuries. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 485.

In 52 injuries, the most frequent symptom of neurovisual involvement was a unilateral optic atrophy. Its direct cause is an injury in the region of the optic canal with subsequent strangulation of the nerve and hemorrhages into its membranes. Injury to the chiasm is rare and usually takes the form of lacerations. In all of the cases of traumatic optic atrophy fractures of the skull were found anteriorly, particularly in the frontal region. Lesions of the fundus were associated with injury to the bony structure of the face. The author believes a post-traumatic optic atrophy is diagnostic of a fracture of the skull.

Mikhailova, M. H. Penetration of six eyelashes into the anterior chamber. *Viestnik Opht.*, 1938, v. 13, pt. 4, p. 548.

In this unusual injury there was a small almost indistinguishable scleral perforation.

Ray K. Daily.

Mitzkevich, L. D. The penetration of eyelashes into the anterior chamber. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 694.

A report of a case, under observation for eight months, in which the presence of an eyelash in the anterior chamber produced no inflammatory symptoms.

Ray K. Daily.

Onfray, R., and Pirot, G. Concerning localization of intraocular foreign bodies and their extraction. *Bull. Soc. d'Opht. de Paris*, 1938, no. 2, Feb., p. 58.

A case is reported in which a magnetic foreign body was localized at the ora serrata. Attention is directed to the harm that may be done by using too strong a magnet, and so wounding the

structures as greatly as at the time of penetration. The advantage of a posterior route of removal is discussed.

Harmon Brunner.

Roche and Farnarier. Prolonged tolerance of a large, unrecognized, intraocular fragment of copper. *Bull. Soc. d'Ophth. de Paris*, 1937, Dec., p. 739.

An atrophying globe which had recently become painful was removed and a piece of copper weighing 0.13 gm. was found. Ten years earlier the eye had been injured by a firearm explosion. No pain or sign of inflammation had been observed previously.

Harmon Brunner.

Sédan, Jean. Extraction of lens containing foreign body for 42 years. *Bull. Soc. d'Ophth. de Paris*, 1938, March, p. 153.

Authenticated record of man blinded 42 years previously by metallic foreign body complicated by iridocyclitis. The extracted lens showed no general lenticular siderosis. An iron fragment was in a small pocket whose walls showed siderosis. (21 references.)

Harmon Brunner.

Sédan, Jean. Partial cataract stationary for six years with foreign body "nailing" iris to lens. *Bull. Soc. d'Ophth. de Paris*, 1938, March, p. 160.

Case report of an eye tolerating a metallic foreign body, which had lacerated the iris and buried itself in the lens. The iris was plastered over the capsular wound. Partial cataract reduced vision to 0.7. The author reviews the literature and summarizes the usual influencing factors in similar cases: age and scleriosis of lens, peripheral site of entry, approximation of wound in capsule. Temporizing is advocated in such cases. (35 references.) Harmon Brunner.

Sverdlow, D. G., and Goldin, L. B. Fracture of the superior maxilla complicated by fracture of the left frontal region, injury to the right optic canal, and total blindness of the right eye. *Viestnik Opht.*, 1938, v. 12, pt. 4, p. 515.

A description of severe injury in a student who was run over by a car. Two days after the injury, when the patient regained consciousness, he complained of total blindness in the right eye, and one month later optic atrophy had developed in the fundus.

Ray K. Daily.

Thies, Oscar. Chemical burns of the eye. *Klin. M. f. Augenh.*, 1938, v. 101, Nov., p. 744.

Injuries of the cornea by bromacetone, war gas, acid vapors, and sulphuretted hydrogen are reported in which early transplantation of labial mucous membrane would have yielded better results. C. Zimmermann.

Veil, P., and Borsotti, I. Experimental study of the extraction of magnetic foreign bodies from the vitreous of the rabbit. *Arch. d'Ophth.*, etc., 1938, v. 2, Dec., p. 1077.

Magnetic pieces of a steel needle were introduced into the vitreous of rabbits, under aseptic conditions. The authors then attempted to remove the foreign bodies by the posterior route after an interval varying from two hours to fifteen days. They conclude that, while the rule of as rapid intervention after the injury as possible holds good, it does not give any operative prognosis. An early attempt at extraction may miscarry, while one performed later may succeed. Intraocular foreign bodies quickly entangle themselves in the ocular tissues. Extraction necessitates laborious maneuvers even in easy

cases. Small particles are more difficult to remove than larger older ones encapsulated in exudate. It is necessary to have a large and a small electromagnet. The latter facilitates removal of small particles which have first been freed by the large magnet.

Derrick Vail.

Yanes, T. R. Industrial eye accidents. *Rev. Cubana de Oto-Neuro-Oft.*, 1938, v. 7, May-June, pp. 57-78.

This is a comprehensive treatise on the management of industrial eye injuries, with tables to calculate the percentage loss of vision, visual field, and ocular motility, and a formula to determine the total percentage disability. A fee schedule for various ophthalmologic services is also given. The author concludes by outlining a number of tests to unmask malingering.

SYSTEMIC DISEASES AND PARASITES

Black, W. B. Ocular manifestations of allergy. *Surg. Gynecol. and Obstet.*, 1939, v. 68, Feb. 15, pp. 406-413.

The role played by allergy in the various ocular diseases is reviewed. Endocrine balance, metabolic and biochemical functions, vitamins, and heredity all play a part in the allergic patient's manifestations. T. E. Sanders.

Charlin, Carlos, Essential facial neuralgia. *Ann. d'Ocul.*, 1938, v. 175, Dec., pp. 894-901.

In fifty cases of essential facial neuralgia treated with tuberculin there were 35 good, 8 mediocre, 7 bad results over a period of one year. One case is described.

John M. McLean.

Goldberg, F. P. Herpes zoster ophthalmicus. *Viestnik Ophth.*, 1938, v. 12, pt. 4, p. 499.

A case involving the left eye developed three days after an acute infection of the throat. The ocular involvement began with an iritis. On the ninth day there appeared signs of keratitis. In the regressive stage of the keratitis two episcleritis nodules, adjacent to peripheral corneal infiltrations, developed at the limbus. There was reduced corneal sensitivity in the right eye.

Ray K. Daily.

Pautrier, L. M. Ocular lesions in Besnier-Boeck-Schaumann disease; syndrome of Heerfordt. *Bull. Soc. Franç. d'Ophth.*, 1938, v. 51, pp. 352-363.

The author notes the same microscopic picture in a number of conditions formerly thought to be distinct, but which he now considers to be related, and which he designates as a true reticulo-endotheliosis. These conditions are: (1) lupus pernio, first observed by Besnier; (2) multiple benign sarcoid, as described by Boeck; (3) benign lymphogranulomatosis, described by Schaumann, which involves the skin, lymph glands, lungs, bones and viscera, and is accompanied by diabetes insipidus; (4) the condition described under the name of "Heerfordt's syndrome," which consists of parotitis complicated by facial paralysis, iridocyclitis, and a skin eruption resembling sarcoid. The microscopic finding identical in all these conditions is an accumulation of epithelioid cells surrounded by round cells, without giant cells or tubercle bacilli.

Clarence W. Rainey.

Shiga, Hidetoshi. Histological study of the eyes of rabbits congenitally infected with syphilis. *Amer. Jour. Ophth.*, 1939, v. 22, Feb., pp. 119-129.

Toulant, P. **Ocular complications in malaria.** *Acta Ophth. Orientalia*, 1938, v. 1, Oct., p. 18.

Among the rare ocular affections due to malaria, dendritic keratitis accompanied by slight trigeminal neuralgia is most often encountered. The keratitis is due to affection of the ophthalmic nerve by the fever, for the plasmodium has never been found in the cornea. Other rare complications are: keratitis ulcerosa and punctata, chorioretinitis, paralysis of the ocular muscles, and transitory optic neuritis (distinguished by melanoid pigmentation on the disc).

R. Grunfeld.

Villiard, Bouniol, Vailfont, and Fuentis. **Twenty-two cases of ocular leprosy.** *Bull. Soc. d'Ophth. de Paris*, 1937, July, p. 348.

A colony of 32 lepers showed 22 with ocular lesions. The incidence of various lesions corresponds with the usual figures; with the exception of scleral lesions, which were few. Final results of intraocular surgery on these patients were invariably poor.

Harmon Brunner.

Werdenberg, E. **Principles of the knowledge and therapy of ocular tuberculosis.** *Klin. M. f. Augenh.*, 1938, v. 100, Nov., p. 641.

This is a short synopsis on ocular tuberculosis from the clinical standpoint, based on experience with about 1,500 tuberculous eye patients. The chief types of ocular tuberculosis, the clinical picture, diagnosis, primary intrathoracic source, general tuberculous disease, diagnosis, and therapy are discussed, with special emphasis on the beneficial effect of high altitude. The author has discarded tuberculin tests and tuberculin treatment on account

of the harm he has seen from all tuberculin preparations. C. Zimmermann.

Wilson, R. P. **Filariasis of the conjunctiva.** *Giza Mem. Ophth. Lab.*, 1937, 12th ann. rept., p. 49.

A male aged seventeen years complained of "something like a serpent moving about in his left eye," noted that day for the first-time. A 10 cm. by 0.5 mm. single filiform cylindrical nematode, possibly *F. bancrofti*, was found moving under the bulbar conjunctiva, apparently trying to cross the corneoscleral margin to the cornea. Before the worm could be removed, it had migrated from the temporal to the nasal side of the globe and back again to the temporal side, from which position it was removed. Lawrence G. Dunlap.

Cosmettatos, G. F., and Charamis, J. S. **The fight against trachoma in Greece.** *Rev. Internat. du Trachome*, 1938, v. 15, Oct., p. 149.

The antitrachomatous organization in Greece is described.

J. Wesley McKinney.

Fonseca, Aureliano. Trachoma among the negroes in the state of São Paulo. *Rev. de Oft. de São Paulo*, 1938, v. 6, Oct.-Nov.-Dec., pp. 195-197.

A brief statistical summary confirms the frequent statement that trachoma is rare in this race. The proportion was approximately of one negro case to one hundred white cases. W. H. Crisp.

Greeff, R. What pictures of Albrecht von Graefe do we possess? 4. Graefe and Bowman. *Graefe's Arch.*, 1938, v. 139, pts. 4 and 5, pp. 587-590.

Two more portraits of Graefe are described and illustrated. One is that of a young man in his student days and the other a picture of Graefe standing with William Bowman.

H. D. Lamb.

Kreiker, A. Blaskovics, L. *Ophthalmologica* (formerly *Zeit. f. Augenh.*), 1938, v. 96, Nov., 9. 73.

An obituary.

Lijo Pavia, J. Trachoma at the school age in Buenos Aires. *Rev. Oto-Neuro. Oft.*, 1938, v. 13, Sept., p. 201.

Eye examination of the children attending the primary schools of Buenos Aires revealed that of 300,000 children, 14,781 suffered from ocular disease, and 135 of these were diagnosed as having trachoma. As might be expected, the highest incidence of trachoma was in the more densely populated parts of the city. The methods employed to check the spread of trachoma are given.

Masters, Robert. Causes of blindness among the children at the Indian State School for the Blind. *Jour. Indiana State Med. Assoc.*, 1938, v. 31, Oct. 1, p. 537.

One hundred and eighty-seven students at the Indiana State School for the Blind are classified according to causes of blindness. Special comment is made concerning cases blind from causes usually considered preventable. These include ophthalmia neonatorum, 15 percent; prenatal syphilis, 12.3 percent; uveitis and its sequelae, 7 percent; and sympathetic ophthalmia, 3 cases.

Turner, Harris. Pensions for the blind in Canada. *Outlook for the Blind*, 1938, v. 32, Dec., pp. 165-168.

A pension system for the blind was established in Canada during March, 1937. At present 3,959 receive pensions, about 38 percent of the total. The maximum pension is twenty dollars a month, with deductions if total income is over two hundred dollars. The definition of blindness is "having less than 10 percent vision."

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Plitas, P. S. The innervation of the motile structures of the eye. *Viestnik Opht.*, 1938, v. 13, pt. 5, p. 645.

The author stained the nerve network of the iris of rabbits in vitro, with a dilute solution of methylene blue. The behavior of the iris thus stained shows that its motions are accompanied by considerable alteration in form and position of the nerve fibers and their endings. The nerves running meridionally are twisted spirally in the dilated iris, and become elongated in the contracted iris. The stained nerves do not permit differentiation between motor, sensory, and sympathetic branches.

NEWS ITEMS

Edited by DR. H. ROMMEL HILDRETH
640 S. Kingshighway, Saint Louis

News items should reach the Editor by the twelfth of the month

DEATHS

Dr. William Gray Ricker, Saint Johnsbury, Vermont, died February 28, 1939, aged 62 years.

Dr. Harry Stearns Willard, Patterson, New Jersey, died December 11, 1938, aged 62 years.

Dr. Walter Hamilton Snyder, Toledo, Ohio, died December 27, 1938, aged 68 years.

MISCELLANEOUS

The staff of the Institute of Ophthalmology of the Columbia-Presbyterian Medical Center of New York City will sponsor a memorial volume of The Collected Papers of Dr. John M. Wheeler, the majority dealing with ophthalmic and plastic surgery. This book will be published in June. Anyone desiring to reserve one or more copies at the cost price of \$4.00 per copy (postage prepaid) should send a check to the Library Committee, Institute of Ophthalmology, 635 West 165th Street, New York City.

The International Association for Prevention of Blindness, which maintains a secretariat in Paris, held its annual meeting in London on Wednesday, April 19, 1939. The principal topic for discussion was "The application of the Credé method for prevention of blindness in various countries." In the United States there has been a 75-percent reduction, during the past 30 years, in the number of cases of blindness from ophthalmia neonatorum. How this was accomplished was related at the international meeting by Dr. Conrad Berens of New York City, a member of the board of directors of the National Society for the Prevention of Blindness. America was represented also by Dr. Harry S. Gradle of Chicago, vice-president of the Illinois Society for the Prevention of Blindness, and Dr. Park Lewis of Buffalo, vice-president of both the International Association and the American National Society.

The American Foundation for the Blind is disseminating as widely as possible information regarding the Talking Book for the blind. This, as its name implies, is a phonographic disc which reads aloud any book which has been read into it. An average book can be recorded on 12 or 15 12-inch discs. One disc will read for approximately 30 minutes. Because of its particular construction for long-playing, the Talking Book cannot be used on an ordinary phonographic machine, but requires the Talking Book machine which was especially designed for it. The several models include machines with and

without radios, electric and springdriven. Seven models are now available, and may be obtained from the American Foundation for the Blind, 15 West Sixteenth Street, New York City, which manufactures and sells them to blind people at cost. Prices range from \$25.00 for a springdriven model to \$120.00 for a console radio-phonograph combination. Price lists giving full information on all models will be sent on request. As many blind people are financially unable to buy these machines, a special grant has been made by the Federal Government for the manufacture of a large number of these instruments to be loaned to such blind people. Information regarding the borrowing of these may be obtained from the American Foundation for the Blind. The Talking Book records may be borrowed by blind people from the 27 regional distributing libraries throughout the country. Among the many Talking Books now available are such titles as "The lost horizon" by James Hilton; "Man of property" by John Galsworthy; "Man the unknown" by Alexis Carrel; "Madame Curie" by Eve Curie; "Snow White"; "Rumbin galleries" by Booth Tarkington; "Journey's end" by R. C. Sherriff; "Sweden, the middle way" by Marquis W. Childs.

Increased activities of the movement for protection of eyesight are reviewed by the National Society for the Prevention of Blindness in its annual report made public recently by Eleanor Brown Merrill, Executive Director. Explaining that its slogan, "Sight for tomorrow—for the world of tomorrow" was selected to conform with the theme of the New York World's Fair, the report adds: "This year, with the lure of things to see in abundance at the Golden Gate International Exposition in San Francisco and at the New York World's Fair, we are forcefully reminded how essential the sense of sight is to enjoyment as well as to work. It would be interesting to conjecture how many, of the thousands traveling eastward and westward, owe their blessing of sight today to those who thought of the world of tomorrow and the saving of sight for that world. The Society's first step, as a local committee in 1908, was an effort to ensure sight for tomorrow by preventing blindness at birth from the disease known as 'babies' sore eyes.' During the past 30 years, the campaign to eradicate this disease—ophthalmia neonatorum—has brought about a 75 percent reduction in the number of

infants who lose their sight at birth. This was accomplished because an organized program was carried on to save sight for tomorrow." The need to intensify the campaign against "babies' sore eyes" is pointed out by the National Society for the Prevention of Blindness. A slight increase in the incidence of ophthalmia neonatorum has been noted recently among boys and girls entering schools and classes for the blind. The latest figure shows an incidence of 7.4 percent as compared to the previous figure of 6.7 percent. Most states now have laws making it compulsory for doctors and midwives to use a prophylactic solution in the eyes of infants at birth as a precaution against this disease.

"The great strides which have been made recently in the campaign for the control of syphilis," the report says, "are of particular significance to the movement for protection of eyesight. Although it is a little early to note the effects of the campaign against syphilis, in so far as sight is concerned, ophthalmologists in one state visited by a representative of the Society commented that fewer cases of syphilitic eye involvements are coming to their attention. It is to be hoped that such reports will become increasingly frequent." Approximately 15 percent of all blindness can be traced to syphilis.

According to the report, sight-saving classes are now providing a normal education for approximately 8,000 American school children who have such seriously defective vision that they cannot be taught in the regular grades. The number of sight-saving classes has grown to 589, an increase of 31 over the year before. Because of the continuous need for specially trained teachers, the Society will participate in the giving of courses for the preparation of sight-saving-class teachers and supervisors at the 1939 summer sessions of the following institutions: Western Reserve University, Cleveland, Ohio; State Teachers College, Buffalo, New York; State Teachers College, Milwaukee, Wisconsin; University of California, Los Angeles, California; Wayne University, Detroit, Michigan.

Approximately 450,000 copies of the Society's pamphlets and 12,000 posters were distributed. A motion picture film, "Preventing blindness and saving sight," was shown to 1,500 audiences. Exhibit material was provided for 125 conventions, fairs, meetings, and so on. A transcribed radio program concerning the dangers to the eyesight of children from the use of fireworks on the Fourth of July was used by 200 stations.

The Society's income for 1938 was \$126,000 and its expenditures amounted to \$169,000, necessitating the use of \$43,000 from its reserve fund. Financial support is received through voluntary contributions from 17,000 members and donors in all parts of the country.

SOCIETIES

The Association for Research in Ophthalmology, Inc., will hold its Tenth Scientific Meeting at the Coronado Hotel, Saint Louis, Missouri, on Tuesday, May 16, 1939. The following program will be presented:

1. Experimental ocular hypersensitivity, by T. E. Sanders, M.D., Department of Ophthalmology, Washington University, Saint Louis.

2. Studies on surface epithelium invasion of the anterior segment of the eye, by T. L. Terry, M.D., J. F. Chisholm, M.D., and A. L. Schonberg, M.D., Massachusetts Eye and Ear Infirmary, Boston.

3. A study of methemoglobin-producing organisms in ocular inflammations, by Maynard A. Wood, M.D., Department of Ophthalmology, University of Iowa, Iowa City.

4. The relation of Müller's orbital muscle to the pathology of retrobulbar tissues obtained in experimentally produced exophthalmos, by George K. Smelser, Ph.D., Department of Ophthalmology, Columbia University, New York.

5. Ocular reactions of horses and rabbits infected with strains of *Brucella* recovered from horses with periodic ophthalmia, by E. L. Burky, M.D., Robert Redvers Thompson, Ph.D., and Helen D. Zepp, A.B., The Johns Hopkins Hospital, Baltimore.

6. Staphylococcus conjunctivitis—experimental reproduction with staphylococci, by James H. Allen, M.D., Department of Ophthalmology, University of Iowa, Iowa City.

7. An immunological study of trachoma, by Louis Julianelle, Ph.D., Department of Ophthalmology, Washington University, Saint Louis.

8. Vitamin-D complex in myopia; etiology, pathology, and treatment, by Arthur A. Knapp, M.D., New York.

The Philadelphia County Medical Society Eye Section presented the following program on April 6, 1939: Posterior ethmoiditis with orbital involvement, by Dr. George W. Mackenzie; Compound prisms resolved and prescribed coincident to cylinder axes, by Dr. Sidney L. Olsho; Sketches on the early history of ametropia, by Dr. Burton Chance; Use of astigmatic dials, by Dr. John Matthews; Ophthalmic aspects of neuro-psychiatry as encountered in a state hospital service, by Dr. Samuel A. Zertsky.

The general assembly of the International Association for Prevention of Blindness was held in London, on Wednesday, April 19, 1939, at the House of the Royal Society of Medicine, 1 Wimpole Street, during the Congress of the Ophthalmological Society of the United Kingdom. The opening address was by Dr. P. Baillart, chairman of the International Association for Prevention of Blindness. The discussion

of the Credé method for the prevention of ophthalmia neonatorum in various countries was opened by Dr. A. H. H. Sinclair (Edinburgh), and continued by Dr. R. P. Wilson (Egypt), Professor F. Terrien (France), Professor von Szily (Germany), Professor L. Maggiore (Italy), Dr. Conrad Berens (United States), and Professor Dr. A. Vasquez Berriére (Uruguay). A film on preventive measures against industrial eye injuries was shown. The printed reports will be distributed to the members of the Association and forwarded on request.

The annual congress of the Ophthalmological Society of Egypt took place at the Memorial Ophthalmic Laboratory, Giza, on March 24, 1939. The symposium for the congress was "Nonsuppurative keratitis."

PERSONALS

Dr. John Dunnington and Dr. Phillips Thygeson have recently been appointed joint professors of ophthalmology of the Institute of Ophthalmology of the Presbyterian Hospital, New York; Dr. Dunnington as chief of the clinical branches of ophthalmology, and Dr. Thygeson as chief of research and teaching.

Dr. Louis Bothman announces the removal of his office from Peoples Gas Building, 122 South Michigan to Suite 1246—310 South Michigan Building. Practice limited to the eye.

Dr. Julian B. Marks announces the opening of his offices in the Beverly Medical Building, 415 North Camden Drive, Beverly Hills, California. Practice limited to eye, ear, nose, and throat.

Kalt, addressing the Société d'Ophthalmologie de Paris, at the recent celebration of its fiftieth anniversary, mentioned the fact that he was the only survivor of the founders of the Society.

Dr. H. L. Cunningham of Cape Girardeau, Missouri, was honored on April 10th at a dinner in celebration of his 50 years in the practice of medicine. Dr. F. E. Woodruff of Saint Louis was the guest speaker.

Dr. Everet H. Wood has opened his office at 120 Genesee Street, Auburn, New York, for the practice of ophthalmology. Dr. Wood has completed his residency training at the Long Island College Hospital. He had also held an appointment as clinical assistant at the Brooklyn Eye and Ear Hospital for 18 months. He also spent 1½ years as Fellow at the Long Island College of Medicine.

During the period of March 22d to March 25th, Drs. P. Chalmers Jameson and John N. Evans conducted intensive instruction courses in ophthalmology under the auspices of the Joint Committee on Graduate Education which includes the Medical Society of the County of Kings, Long Island College Hospital, and the Brooklyn Eye and Ear Hospital. Dr. Jameson's course covered operative technique of the extraocular muscles; Dr. Evans's, advanced instruction in visual field work. Both these courses were well attended, and it is probable that they will be repeated at a later date.

Dr. Walter Moore was recently made a surgeon at the Brooklyn Eye and Ear Hospital, to occupy the position previously held by Dr. James Andrew, who died a few months ago.

Dr. Charles Rosenthal has recently been appointed clinical assistant under Dr. Evans at the Brooklyn Eye and Ear Hospital.

The Brooklyn chapter of the American College of Surgeons visited the Department of Surgery at the University of Rochester, New York, on March 11th. This group included a unit composed of the following ophthalmologists: Drs. Walter Moore, Charles A. Hargitt, P. Chalmers Jameson, William F. Steinbugler, and John N. Evans.

Dr. Jonas Friedenwald presented a paper before the Pediatric Section of the Medical Society of the County of Kings in Brooklyn on February 15th. His subject was "The vitamin problem in the domain of ophthalmology."

Drs. Charles R. Hopkins and Harold Schilback have recently been appointed to a special committee for the New York Board of Education to investigate the general problem of sight-conservation classes as they now exist in schools.

GUMMA OF THE ORBIT*

MAX FINE, M.D.

San Francisco

Of all the conditions in which the ophthalmologist must make a differential diagnosis the most difficult is that of unilateral exophthalmos. Excluding the acute phlegmons of the orbit, cavernous-sinus thrombosis, and arteriovenous aneurysm, in which the diagnoses are usually obvious, every ophthalmologist has been confronted with the patient who has a slowly progressive exophthalmos in which the diagnosis has been most obscure, sometimes made only through the natural history of the disease, and sometimes not made at all. One of the conditions producing such exophthalmos, which because of its rarity is unfortunately often not considered till late, is gumma of the orbit.

CASE REPORTS

Case 1. A negress, aged 37 years, presented herself on March 16, 1937, complaining of pain and impairment of vision in the left eye of two weeks' duration.

The patient stated that she had first noted intermittent diplopia about one month previously. At that time she had begun to experience an aching pain in the left eye, radiating to the left frontal area. One week after the onset the diplopia disappeared and she noticed that the vision in the left eye was poor. She consulted an optometrist, who prescribed lenses. The pain became more severe and continuous, keeping her awake at night. The vision continued to decrease, and upon returning to the optometrist the pa-

tient was advised that she needed a stronger lens. At this time she observed that the eye protruded slightly and the lid drooped, and came to the Stanford Eye Clinic for advice.

In December, 1930, the patient had had an ischiorectal abscess, associated with extensive rectal strictures. The blood Wassermann had been four plus; the patient, however, denied any symptoms of primary or secondary lues. Continuous antiluetic therapy was given through 1931, consisting of neosalvarsan, mercury, and bismuth injections. She had received no treatment since that time. A blood Wassermann test taken in December, 1936, had been strongly positive, but the patient had failed to return for further treatment.

Ocular Examination: Vision in the right eye was 15/15, there was no evident pathology and the visual field was normal. In the left eye there was no light perception. A moderate ptosis was present, the lid margin covering the upper half of the pupil. The globe protruded slightly, directly forward. The exophthalmometer reading for the right eye was 18.5 mm.; for the left eye, 20.5 mm.

Except for slight upward rotation, less than five degrees, the left eye was immobile (fig. 1A). The little finger could be inserted between the orbital margin and the globe in all meridians to the equator without encountering abnormal resistance. The pupil was semidilated, slightly irregular, and failed to react to direct light. A prompt consensual reaction was ob-

* From the Department of Ophthalmology, Stanford University School of Medicine.

tained and a prompt reaction to convergence. Corneal sensitivity was normal. The optic disc was slightly pale in the temporal half and the markings of the lamina cribrosa were more prominent than

The ocular rotations were normal except for a slight weakness of the inferior rectus (fig. 1, B). The exophthalmos had receded completely. Light perception was present and there was a good pupillary

Fig. 1 (Fine). Case 1. A, as of March 17, 1937; B, as of May 8, 1937.

in the right eye. Sensation over the distribution of the supraorbital nerve was normal.

Upon general examination, no clinical evidence of lues was found. Laboratory examinations were negative as to the spinal fluid and urine. An X-ray study of the orbit showed no pathology.

Impression: Gumma of the left orbit.

Treatment: The patient was given injections of iodo-bismutol twice weekly and potassium iodide 40 grains daily. On April 23, 1937, a very slight ptosis remained.

reaction. The pallor of the disc had increased somewhat.

On May 21, 1937, the patient was able to count fingers at about one foot in the nasal field. There was no central nor temporal vision. Ocular rotations were entirely normal. The disc had become very pale. The blood Wassermann was now negative. Bismuth and potassium iodide were discontinued, and a course of neoarsphenamine was begun.

Case 2. A Negress, a domestic, aged 27 years, divorced, presented herself on De-

cember 10, 1937, complaining of a swelling over the right eye of two months' duration and severe headache for the past two weeks.

The patient stated that about two months previously she had noticed a small nontender nodule at the upper margin of the orbit. This nodule had slowly increased in size to the present time. In the past two weeks the swelling had been somewhat tender and during this time

of the upper lid, but the pupil remained uncovered. The upper lid showed diffuse, nonpitting edema with slight erythema. A smooth, rounded nodule, about 1 cm. in diameter, of rubbery consistency, slightly tender, was attached to the middle portion of the supraorbital ridge. The nodule was only slightly movable. Its lower margin could not be accurately outlined because of the surrounding edema—it appeared to continue under the margin

Fig. 2 (Fine). Cast 2. A, as of December 13, 1937; B, as of January 27, 1938.

also she had experienced severe frontal and parietal headaches, which had become increasingly worse and were most severe during the night. At times the pain seemed to arise in the right orbit and radiate upward. During the past month she had had a chronic running nose, as from a head cold, and had noticed that the senses of smell and taste seemed diminished. One week previously, while blowing the nose, she had discharged a small piece of bone "like crab shell" from the right nostril. She had felt well generally and there had been no loss of weight. There had been no impairment of vision.

The patient denied any history of luetic symptoms or anti-luetic treatment, by name and description. No blood test had been taken prior to the present illness.

Ocular Examination: Vision in the right eye was 15/40; corrected to 15/15 each eye.

Right eye: There was a moderate ptosis

of the ridge into the orbit for a short distance. There was slight edema and redness of the lower lid (fig. 2, A). Sensory discrimination over the distribution of the supraorbital nerve was normal. The conjunctiva of the lids was slightly hyperemic. The cornea was clear; its sensitivity normal. Iris and pupil showed normal reaction to light and convergence, with normal consensual reaction. The tension (digital examination) was normal. Ophthalmoscopic examination of the fundus showed no abnormalities of the disc, retina, or vessels. The extraocular muscles allowed normal rotations in all directions. The visual fields were normal—3/330 white and 2/330 red and green.

Physical examination: No abnormalities were found except in the nose. The right septum was convex in its mid portion with an ulcerated granular mass touching the middle turbinate. The left side presented a similar appearance. A probe introduced in this area passed

through the septum, there being a perforation at the junction of the cartilage and the vomer.

Laboratory examination: An X-ray film of the orbit revealed no pathology. The blood Wassermann reaction was four plus.

Impressions: Gummatous periostitis of supraorbital ridge; gumma of nasal septum with perforation.

Treatment: Antiluetic treatment was begun in the syphilis clinic on December 16, 1937, with prescription of sobisminol (oral bismuth) 1.2 gm. daily. On December 27, 1937, there was a definite decrease in the size of the tumor. The patient stated that she had regained the sense of smell. There was no evidence of bismuth toxicity. On January 6, 1938, a very marked decrease in the size of the gumma had taken place. A small, nontender nodule the size of a hazelnut could now be felt, attached to the under surface of the superior orbital margin (fig. 2, B). The patient had been free from headaches or pain for two weeks.

January 27, 1938, the blood Wassermann test was repeated: four plus.

By February 10, 1938, there had been complete involution of the gumma. Only a slight residual thickening of the orbital margin remained. Examination on February 24, 1938, showed no difference between the right and left orbits.

DISCUSSION

The two cases of gumma of the orbit reported herewith are the only two on record in the Stanford Clinic since 1913, in which year the present system of records was begun. During this period approximately 40,000 patients were seen in the eye department and 271,000 in all departments. Kemp¹ reported that of 6,000 cases of syphilis at the Johns Hopkins Hospital only five cases of orbital syphilis occurred, and stated that he had collected

150 cases of syphilis of the orbit from the literature. Birch-Hirschfeld,² at the Leipzig clinic, found that syphilis of the orbit constituted .01 percent of ocular disease. All of these statistics indicate that the condition is very rare. The author, reviewing the available literature of the past 25 years, found 24 reported cases in which the diagnosis of orbital syphilis was established. The numerous cases of orbital pseudotumor in which the Wassermann reaction was negative and in which there was no history or clinical evidence of syphilis have not been considered in this review, although undoubtedly a number of these that vanished under administration of potassium iodide must have been gummas. For brevity these cases are presented in tabular form.

It is interesting to note that of the 24 recorded cases, 5 were bilateral, although the onset was not simultaneous in the two orbits. It is probable that this apparently high incidence of bilateral occurrence of orbital gumma may be explained by the fact that many unilateral cases are not reported, while the unusual feature of bilaterality is reported more constantly. It is possible, however, that an organotropic mechanism may be concerned, witness the relative frequency of bilateral luetic uveitis.

Diagnosis. The common symptoms and signs that lead to a diagnosis of orbital gumma are pain, exophthalmos, and impairment of function of one or more of the nerves within the orbit; namely, the optic nerve, oculomotor, trochlearis, abducens, and the ophthalmic and maxillary divisions of the trigeminal. The extent of this involvement depends on the situation, size, and duration of the lesion. The instances of orbital gumma may be divided into two anatomical groups—those that occupy the apex of the orbit and those that involve the marginal portion of the orbit, including the lacrimal fossa. The two cases reported here are prototypes

of these two groups. Obviously the marginal lesions will produce no exophthalmos nor nerve palsies. Pain, however, is a common symptom and may be very severe, radiating to the frontal region and to the eyeball. This symptom is frequently the first and may precede other signs and

symptoms by weeks or even months. Severe orbital pain or frontal headache are described as the initial symptoms in eight of the recorded cases. Increased intensity of the pain at night appears to be characteristic. The neoplasms of the orbit are, as a rule, painless, and the symptom of

pain may serve as a valuable differential sign (Igersheimer²). When the lesion is situated near the rim of the orbit there is usually some tenderness to pressure, though not very marked. The pain of an intraorbital gumma may be increased when pressure is made on the globe.

Exophthalmos is a constant sign of intraorbital gumma. The superior wall of the orbit is the most common site of origin and the resulting displacement of the globe is usually directly forward or forward and downward. The exophthalmos is not reducible by pressure; this may

serve as a differential sign in ruling out proptosis due to angiomas of the orbit or orbital edema associated with infections of the regional paranasal sinuses. Pressure of the gumma on the veins may produce congestion of the orbit and contribute to the exophthalmos. Kemp has described dilation of the veins of the temple in association with such a lesion. X-ray examination of the orbit is usually of little diagnostic aid, the findings usually being negative. Raffin⁴ describes two types of orbital syphilis: (1) an exudative hyperplastic periostitis with thickening of the periosteum; (2) a gummatous periostitis with a circumscribed tumor of soft consistency. The latter type, occurring in the tertiary stage, is the more common and this fact probably explains the absence of positive X-ray findings.

Involvement of the extraocular muscles through pressure paralysis of the motor nerves occurs in practically every case of intraorbital gumma. This involvement progressed to complete immobilization in one third of the collected cases. Paresis of the external rectus is the most common onset of the immobilization. Ptosis and superior-rectus paralyzes are next in frequency.

The optic nerve may be affected in several ways. Most often there is papilledema followed by secondary atrophy. Occasionally, there is optic atrophy without signs of congestion. Kemp mentions retrobulbar neuritis followed by atrophy as occurring frequently, but a review of the reported cases does not bear this out. In our second patient there was complete blindness with only a slight pallor of the disc. This was followed by optic atrophy of the primary type.

Paresthesias of forehead and cheek may occur from irritation of the first and second branches of the trigeminus. Depending on whether the nerve involvement is in the irritative or destructive

stage, there may be hyperesthesia or hypesthesia. Keratitis neuroparalytica has been reported rather infrequently, complete anesthesia of the cornea being uncommon.

The Wassermann reaction is important in the diagnosis of gumma of the orbit, and, indeed, in most cases the diagnosis rests on the presence of one or more of the signs described above and a positive Wassermann reaction. It is, however, to be kept in mind that in 6 of the 26 collected cases (22 percent) the blood Wassermann was negative. In one of these the spinal fluid was positive.

Treatment. As with gummas elsewhere, there is probably no disease in which the results of treatment are as gratifying as in gumma of the orbit, provided it is instituted before the nerve changes have become irreversible. Recovery usually comes within three to six weeks irrespective of the type of antiluetic therapy used. The combination of potassium iodide with one of the heavy metals (mercury or bismuth) as in other late luetic processes, affords a safe and effective antiluetic therapy.

It must be remembered that the response to antiluetic therapy is not always immediate. In several of the cases reported no decrease in exophthalmos was noted until three weeks had elapsed. Where a therapeutic trial is being made, in the presence of a negative Wassermann reaction, therapy should not be abandoned for at least one month. In the case reported by Kalt,⁵ antiluetic therapy was given for two months without improvement. When biopsy proved the lesion to be a gumma more intensive therapy was instituted, with good recovery. When potassium iodide is used the dosage should be adequate (40 to 100 grains daily). The minute doses which are often prescribed only serve to confuse the diagnosis.

In any case of suspected orbital tumor in which the diagnosis is not apparent, a therapeutic trial of antiluetic therapy is indicated, regardless of the Wassermann reaction. This rule, stated by Meller 25 years ago, has been made no less applicable today by the advances in syphilology and ophthalmology.

LECTURES ON MOTOR ANOMALIES*

X. SUPRANUCLEAR PARALYSES

A. BIELSCHOWSKY, M.D.

Hanover, New Hampshire

The disorders of the movements of the eyes caused by lesions of peripheral origin—namely, of the nuclei and the individual motor nerves—have been discussed previously. If a lesion is situated above the nuclei, injuring the supranuclear apparatus—that is, the pathways between the nuclei and the cortical, the sub-cortical, or the vestibular centers—paralysis of associated muscle groups of both eyes occurs as a rule. The few exceptions to this rule are the paralyses caused by a lesion of the posterior longitudinal bundle or those in the immediate neighborhood of the nuclei of the oculomotor nerves. Such a lesion can deprive one internal rectus muscle of the faculty of adduction in lateral movements, leaving intact its convergence function, or it can make the elevator muscles of one eye incapable of producing a voluntary elevation without disturbing the involuntary elevation that takes place in Bell's phenomenon. Theoretically, supranuclear paralyses of the other individual ocular muscles are quite conceivable, but there is no way of differentiating between supranuclear and peripheral disturbances of those muscles, because they do not act as parts of different mechanisms in anything like the same degree as the internal rectus muscles act in lateral and in convergence movements, or as the elevators act in obeying the elevation impulse and the impulse to shut the eyes. Therefore, but for the few exceptions just mentioned, the diagnosis

of a supranuclear lesion is based chiefly on bilateral and equal paralysis of associated muscle groups.

I shall discuss, first, associated paralysis of the parallel lateral movements, the symptoms of which have been studied mostly in paralyses caused by lesions of the associated pathways either within or near the pons and the region of the fourth ventricle. In an uncomplicated case of this type, both eyes being unable to move to the right, for instance, are deviated slightly to the left. This deviation induces the patient to turn his head a little to the right in order to look at an object straight in front of him. No diplopia is present because of the equality of the deviation of the two eyes. When the patient is ordered to look at an object on the right, neither eye can move beyond the midline; or if the movement is not completely lost, the restriction of the movement is equal in both eyes, so that binocular single vision is not disturbed. In such a case jerky nystagmus to the right reveals the repeated futile efforts to direct the eyes toward the object in the right periphery of the field of fixation. Strict proof of the supranuclear origin of such a paralysis is given by the intact convergence function of the left internal rectus muscle, which is unable to advert the left eye only when a parallel movement is called for, whereas its reaction to convergence impulses is normal. From this behavior it must be concluded that the nerve to the left internal rectus and its nucleus, as well as the pathway descending to the latter from the convergence center, are intact, but that the pathway descending from the cortical center governing the associated

*From the Dartmouth Eye Institute, Dartmouth Medical School. Read before the Seventh Annual Mid-Winter Clinical Course of the Research Study Club, Los Angeles, California, January, 1938.

movement to the right has been interrupted. However, it is still to be ascertained whether the paralysis of the right external rectus muscle is also caused by a supranuclear lesion. It is quite possible that a lesion of the right abducens nucleus involves the posterior longitudinal bundle as well, so that the left internal rectus fails to function when innervated together with the right external rectus. The deci-

acter of the ocular movement that had just been produced. In a second test, while the patient was fixating an object straight in front of her I rotated her head *slowly* to the right. Again the eyes moved to the left as far as in the first test, but this time they were able to maintain fixation and to remain directed to the left as long as the head was kept rotated to the right, a proof that this time the ocular

Fig. 50 (Bielschowsky). Associated paralysis of levoversion caused by an acute encephalitis pontis. A, the two eyes do not respond to the maximal levoversion impulse while (B) dextroversion, as well as (C) convergence are executed perfectly. By turning the patient's head with a sudden jerk to the right (D), levoversion to an almost normal extent can be obtained, but the eyes move back toward the original position immediately after the rotation of the head is completed. (When the photograph reproduced in D was taken, the two eyes were already moving back from the extreme levoversion toward the middle position.)

sion will depend on how the right abducens nerve responds to a vestibular stimulation.

In 1901, I¹ had under observation a patient with an acute encephalitis that was localized in the pons, and had produced an associated paralysis of the parallel movement to the left, with no disturbance of the convergence function of the internal muscles (fig. 50). The patient was unable to move her eyes to the left at command, and was also unable to look at an object situated in the left half of her visual field. In the face of the apparently complete inability to move the eyes to the left, the result of the further examination was all the more surprising. While the patient was fixating an object straight in front of her I rotated her head with a sudden jerk to the right. The result was that both eyes moved to the left to a nearly normal extent, but immediately after the rotation of the head had been completed the eyes went slowly and involuntarily back to their original position—a proof of the genuine reflex char-

movement was caused not by a vestibular reflex action but by an innervation of cortical origin. The same effect was obtained when, instead of rotating the patient's head, the object looked at was carried very slowly to the left. Both eyes maintained fixation and followed the object as far as in the other tests and remained directed to the left for a considerable time. The ocular movement to the left produced in such a manner I called "Führungsbewegung"; Duane calls it the "following movement." It arises from the same cortical innervation as the ocular movement in the second test. I shall try to explain later how the different results arise that are obtained by making use of the tests described.

By far the most frequent of the associated paralyses of the vertical movements are the paralyses of elevation, next in frequency are the paralyses of both elevation and depression, and the rarest are the paralyses of the depression movement. In 1906 Steinert and I² reported on a series of cases of paralysis of the associ-

ated vertical movements, the characteristic signs and symptoms of which are shown in the following case report:

A man, aged 48 years, had paralysis of the elevator and depressor muscles following a paralytic stroke. He was unable to look either up or down at command and was likewise unable to fixate an object in his visual field above or below the horizontal plane. When he sat opposite a vision test card so that the largest letter was on a level with the horizontal plane of his eyes, he could read the largest letter but was unable to read the letters in the next line below. That this was not due to a deficiency of vision was easily proved. If the card was raised gradually the patient could read each of the lower lines as soon as it came up to the horizontal plane, thus showing that he had normal visual acuity. But after he had read the lowest line he was unable to read the larger letters, because they were at that time situated above the horizontal plane.

The same result was obtained if, instead of raising the test card, prisms of increasing strength were placed base down before the patient's eyes. He was then able to read the lower lines. When the prisms were placed base up they helped him to read the letters above the horizontal plane. But when a card with the largest letters on top was brought to the horizontal plane, a prism of 10 degrees placed, base up, before each eye made the letters illegible; similarly, if the prisms were placed base down before his eyes, the letters on the lowest line became illegible. In other words, the patient was unable to compensate for a prismatic displacement of even 5 arc degrees by a corresponding vertical ocular movement. In striking contrast to this result was the ability of the patient's eyes to follow an object to an almost normal extent when it was moved *slowly* up and down and to remain in the elevated or depressed posi-

tion for a considerable time. But they were unable to return to the horizontal plane from either position without being led by the guiding object.

Another interesting experiment was as follows: The patient sat opposite a vertical tangent scale, the fixed light in the center being on a level with his eyes. At the word of command he was unable to direct the visual lines at one jump to one of the more distant numbers—for instance, to the number 5 above or below the light—whereas he succeeded in turning his eyes gradually and with a noticeable effort from the light to the number 1, from 1 to 2, and so on up to the upper or down to the lower end of the scale. It was not a normal movement, but a slow creeping of the eyes along the successive numbers above or below the light. A quick vertical movement of the patient's eyes up or down to their normal limits could be produced only when his head was turned passively up or down with a sudden jerk. In Germany this behavior is called "Puppenkopffphänomen" (doll's head phenomenon). But, as in paralysis of the lateral movements, immediately after the cessation of the passive rotation of the head, the eyes glided back automatically to the original middle position.

Finally, Bell's phenomenon was looked for. When the patient was asked to shut his eyes they went upward to the normal extent.

In some cases Bell's phenomenon is the only proof of the integrity of the nuclei in bilateral paralysis of the elevator muscles (fig. 51).

What is the significance of the various results obtained through examination of the associated paralyses by means of the methods just described? They make it possible not only to decide that a paralysis has been caused by a supranuclear lesion, but also, at least to a certain extent, to localize the lesion more precisely, since it

can be determined which of the various pathways descending to the nuclei are intact and which have been injured.

Barany's tests for ascertaining vestibular excitations present an essential improvement in the examination of the patients with associated paralyses. They can be used for bedridden or somnolent patients and, further, since the vestibular stimulus continues for about a minute, its effect can be observed much better

water at 20°C. is syringed into the right auditory passage; from 10 to 20 seconds later labyrinthine nystagmus toward the opposite side arises if the vestibular apparatus is intact. If the patient is unconscious there will be no nystagmus but only a slow movement of labyrinthine origin toward the same side; that is, in the example chosen it will be toward the right, even if there is an associated paralysis of dextroversion of supranu-

Fig. 51 (Bielschowsky). Associated paralysis of the elevator muscles caused by a tumor of the corpora quadrigemina. A, in the usual position of the eye, both visual lines are equally depressed. B, the visual lines can be raised voluntarily or at a word of command only to the horizontal plane. C, they cannot pass even if the fixed object is slowly moved upward. D, only in Bell's phenomenon, if the patient is asked to close his eyes, is a maximum elevation obtained, proof of the supranuclear localization of the lesion. E, the eyes have regained the faculty of moving upward after removal of the tumor.

than in the head-rotation test, which produces only a momentary excitation. Without going into the details of the various Barany tests, I wish merely to give the following data. The patient sits on a revolving stool that is rotated about 10 times. The vestibular stimulation that results from the current thus set up in the endolymph of the semicircular canals produces a labyrinthine (jerky) nystagmus toward the side of the rotation; a sudden discontinuance of the rotation brings about a secondary nystagmus in the opposite direction, lasting from 30 to 40 seconds, provided the vestibular apparatus and its connections with the nuclei of the paralyzed muscle are intact. If the patient is bedridden, somnolent, or a young child, the caloric test is preferable. After it has been ascertained by examination that the ear is normal, as it must be,

clear origin. If, however, the right eye lags behind, it must be inferred that the nucleus of the abducens nerve or the nerve itself is injured.

As long as the paralyzed muscles respond to vestibular stimulation it may be assumed that there is integrity of the nerves, their nuclei and the pathways connecting them with the vestibular apparatus. In many instances, although a patient with this type of paralysis is unable to turn his eyes in the direction of an object or sound, either at word of command or spontaneously, he can do so if an object which he is asked to fixate will be moved in that direction. How this "following movement" is released and where the innervation concerned arises, is still an unsolved problem. Since there are several centers in the cerebral cortex—in the frontal, in the occipital, and in the

temporal lobe—that are concerned with the associated movements, some authors supposed that the innervations causing the “following movement” and the willed or commanded movement are derived from different centers and pathways, so that a lesion which interrupts the pathway descending from the frontal lobe makes the voluntary movement disappear while the following movement may not be disturbed. However, many patients, although they are able to follow a moving object, lack the ability to make an “attraction movement”; that is, to turn the eyes toward an outlying object the image of which, situated in the periphery of the retina, attracts their attention.

Both kinds of movement belong to the so-called psycho-optic reflexes because, being produced by visual stimuli, they are performed more or less instinctively, so that one is justified in locating the origin of these movements in the occipital lobes. In spite of the fact that only the attraction movement can be lost while the following movement remains more or less intact, it is not necessary, in my opinion, to assume that they have separate centers and pathways. The patient, whose case was cited as an example of associated paralysis of vertical movements, was unable to overcome a prism of 10^Δ , base down or up, by elevation or depression of the visual lines, nor was he able to turn his eyes from the fixated point to an object, the image of which was situated 5 degrees above or below the retinal centers. But he accomplished vertical movements of 10 arc degrees and more when he was given prisms of gradually increasing strength, beginning with 1 or 2^Δ , or when he was induced to turn his eyes to an object which was situated near the fixed point, either above or below it, and from that object to another nearby, so that the eyes performed a sort of climbing along a vertical series of objects that were close together.

This behavior strongly suggests a comparison with fusion movements which are independent of the will. From testing the vertical duction power, for instance, it is known that one is unable, in the beginning, to overcome a prism of 5^Δ or more. But by beginning with a prism of 1^Δ or 2^Δ and gradually increasing the strength of the prism one can overcome from 8^Δ to 10^Δ by the appropriate vertical divergence. Such a fusion movement as well as the following movements in cases of associated paralysis may be explained in the same way. The nearer the image which attracts attention is situated to the fovea, the stronger is the motor effect that is produced. If a weak prism is placed, base out, before one eye, adduction takes place involuntarily, whereas a strong prism in the same position does not, as a rule, produce that movement. If the pathway descending from the occipital center is injured but not fully interrupted, the patient may be unable to perform an attraction movement of great extent, but he is able to make a small movement induced by the excitation of a paracentral retinal point. When the fixated object is moved slowly or the strength of the prism is increased little by little so that the retinal image of the fixated object moves from the fovea to a place in its proximate vicinity, a new small compensating movement results which becomes considerable in extent. This theory of mine must still be proved, but it takes into consideration all the clinical signs and symptoms, especially the fact that the following movement can be produced by moving the object across the field of fixation very slowly, or by turning the patient's head very gradually in the opposite direction. Unlike the sharp jerking of the head, such slow rotation causes no vestibular reflex movement.

According to the particulars which can be ascertained by the various methods of investigation, it may be possible to make

an approximate localization of the lesion causing the associated paralysis in an individual case. "Pseudo-ophthalmoplegia," so-called by Wernicke since he saw it as a partial manifestation of pseudobulbar paralysis, displays the following characteristics: The patient is unable to move his eyes at word of command, but moves them involuntarily in states of emotion or if he is interested in an object or in a sensory excitation originating from an object. The following movements can be produced provided the patient's attention is attracted to the moving object. The reflex movements of vestibular origin are undisturbed. In some of these cases the whole oculomotor apparatus, including the cortical centers, is uninjured, the lesion being "transcortical," injuring the connections between the frontal oculomotor centers and other parts of the cortex. Similar symptoms occur in diseases of the extrapyramidal system.

More frequently one encounters a second group of associated paralyses, characterized by the patient's inability not only to move the eyes in a certain direction either voluntarily or at word of command, but also to move them toward an object attracting his attention. The following movement and the reflex movements of the eyes can, however, be produced. In this group the lesion is to be localized below the cortex; probably the pathways descending from the frontal centers are injured not far above the nuclear region.

In a third group the paralyzed associated muscles react only to reflex (vestibular) stimulation; neither the voluntary and attraction movements nor the following movement can be produced. In cases of paralysis of the lateral movements the internal rectus muscles are able to perform the convergence movement; in cases of paralysis of the vertical movement the elevator muscles may be able to function

in Bell's phenomenon. In such cases the lesion must be localized closely above the nuclei, the posterior longitudinal bundle being intact.

In a fourth group the paralyzed muscles do not respond to visual or other sensory stimuli, or to word of command, nor are they able to perform a following movement or, lastly, a reflex (vestibular) movement. In such cases either the posterior longitudinal bundle or the nuclei themselves must have been injured. The latter supposition is untenable in cases of paralysis of the lateral movements if the internal rectus muscles are able to produce a convergence movement and in cases of paralysis of the vertical movements, if Bell's phenomenon is undisturbed.

In the last group of associated paralyses there are not only symptoms of a supranuclear lesion, but also signs and symptoms indicating an injury of the nuclei, such as paralytic squint and diplopia and a variation in the behavior of the paralyzed muscles according to the mode of stimulation.

The cases of associated ocular paralysis caused by lesions within the cerebral hemispheres are usually unsuitable for precise investigation, partly because of the bad mental condition of the patients and partly because of the quick recovery of ocular movements if the patient does not die. It may be supposed that in some cases an examination would reveal almost the same symptoms as in cases of pseudobulbar paralysis, which have already been discussed as the first group of associated ocular paralyses.

CONJUGATE DEVIATION

Conjugate deviation, which is found in most cases of a recent cerebral lesion, may be caused by a variety of circumstances. If an associated pair of muscles is paralyzed in consequence of a lesion

of the cortical center or of the path descending from it, the antagonistic pair of muscles ceases to receive its inhibitory innervation at the same time, because the excitatory and the inhibitory impulses to the agonists and antagonists, respectively, are derived from the same center and from the same pathway, so that a lesion of one not only causes paralysis of the agonists but also prevents relaxation of the antagonists. Besides the loss of inhibitory impulses, a stimulation of the antagonists may be caused by a lesion that extends to the other hemisphere. The different causes of conjugate deviation make it easy to understand that in cases of cortical lesions the deviation, as a rule, is greater than in cases of supranuclear paralysis of pontine origin and that it sometimes disappears within a few hours—as soon as the patient regains consciousness. Even if the conjugate deviation is essentially paralytic, it usually disappears rather quickly, probably because there are centers in both hemispheres for the parallel movement to the right and left, so that

the center of the sound side soon begins to function vicariously. In the examples under discussion the patient's head is turned in the same direction as his eyes—that is to say, to the side of the lesion—except in those cases of hemiplegia which are characterized by contracture of the limbs. In these cases the eyes and the head are turned toward the affected extremities.

The accompanying table offers a comparison of the paralyzes of lateral movements caused by pontine lesions and those caused by lesions in the hemispheres.

PARALYSES OF CONVERGENCE

Since it is known that the internal rectus muscles can be deprived of the ability to coöperate with the external rectus muscles in lateral movements without interference with their convergence function, it seems obvious at first glance that the latter function can also be lost without prejudice to the former. It is not known where the convergence center is located. In view of the fact that convergence

Lesions of the Hemispheres

1. Deviation in the first stage, regular and of considerable magnitude.
2. Deviation usually of short duration.
3. Deviation toward the side of the lesion.
4. Deviation frequently a symptom of stimulation.
5. Head turned (as a regular symptom) in the same direction as the deviation of the eyes.
6. Associated paralysis of the muscles for contralateral movement, usually slight and transient.
7. Invariably symmetrical functional disturbance of the associated muscles.
8. Paralysis of the extremities and of the facial nerve collateral with the associated eye-muscle paralysis.
9. In lesions of both hemispheres all eye movements (including the vertical) restricted or impossible.

Pontine Lesions

1. Deviation relatively rare and, as a rule, of small magnitude.
2. Deviation, if present, permanent.
3. Deviation toward the opposite side.
4. Deviation usually a paralytic symptom, only rarely a stimulation symptom.
5. Abnormal position of the head not a typical symptom; if present, the head usually turned in the opposite direction to the deviation of the eyes.
6. Associated paralysis in the direction of the lesion, nearly always severe and permanent.
7. Frequently asymmetrical paralysis of the associated muscles in consequence of the extension of the supranuclear lesion to the nucleus or the nuclei.
8. Paralysis of the extremities, if present, opposite to the side of the eye-muscle paralysis; paralysis of the facial nerve, if present, usually collateral with the eye-muscle paralysis.
9. In pontine lesions of both sides, paralysis of side-to-side movements without disturbance of the vertical movements.

paralyses are frequently caused by lesions within the region of the corpora quadrigemina, it is presumed that a subcortical convergence center is located in that region; the isolated lesion of this center or of the pathway descending to the nuclei of both internal rectus muscles must produce the symptoms of a pure convergence paralysis. In such a case the patient's eyes are unable to converge, whereas the internal rectus muscles function normally when coöperating with the external rectus muscles in parallel movements. There is crossed diplopia of near objects, whereas objects at a distance of more than one meter are seen single provided the convergence paralysis is not complicated by an exophoria. Even a slight degree of exophoria causes insuperable crossed diplopia of distant objects if the convergence is abolished completely. The angle of deviation is the same when the patient looks straight forward or to either side, but it is increased not only when he looks at near objects but, as a rule, also when he looks up, and is decreased when he looks down, for the anatomic reasons mentioned previously. Variations of the signs and symptoms occur according to whether there is complete paralysis or only more or less weakness of the convergence function.

The convergence paralyses of organic origin are rare. Many of the cases published are no doubt instances of functional disturbances that are not always easy to distinguish from true organic paralyses. This difficulty is based on the exceptional position of the convergence among the ocular movements. Convergence does indeed belong to the fusion movements, but it is the only one that can also be performed voluntarily. If binocular single vision is lost or has never existed, as in cases of strabismus acquired in early childhood, the ability to converge is more or less diminished or is absent, thus prov-

ing that the fusion tendency is the most essential factor in producing convergence, whereas the voluntary impulse to look at a near point is of secondary importance in bringing convergence into play. In spite of equally good vision in either eye, convergence is frequently defective or absent, especially in myopic persons who do close work without glasses. Since they see distinctly at their *punctum remotum* they avoid the fusion effort which is not assisted by the accommodation impulse, and learn to suppress the retinal images of the nonfixating eye.

Lastly, an insufficiency of convergence as a true functional neurosis is encountered rather frequently not only in anemic and delicate persons or in patients convalescing after exhausting illnesses, but also as a symptom of general neurasthenia or hysteria. Conditions of this type are sometimes diagnosed wrongly as convergence paralysis because convergence cannot be produced by means of the usual methods. No convergence is obtained if the patient is ordered to fixate a near object, for instance, his own finger, or the fissure of Landolt's ophthalmodynamometer. But these tests do not offer reliable proof of the presence of a convergence paralysis unless it is ascertained that the patient has really been given the required impulse to look at the near object. This can be determined by observing his accommodation and pupils during the tests. Only if the pupils contract and the refraction increases according to the distance of the near object can one be certain that the deficiency of convergence is due to an organic lesion. I remember a patient who complained of a permanent crossed diplopia in near work after an accident. She was said to be an invalid after several oculists had submitted a diagnosis of convergence paralysis of traumatic origin. When her eyes were tested in the usual manner there was no

convergence. Since there was no accommodation and the pupils did not react in the tests I tried to ascertain whether the absence of cortical impulses was voluntary or involuntary. I asked the patient to tell me to which number the minute hand of my watch was pointing. She promptly produced the corresponding convergence, accommodation, and pupillary action. I have seen several similar cases in which the patient at first seemed unable to converge but could be induced to do so when he was tested with objects which attracted his attention and interest.

Another method suitable for deciding whether the lack of convergence is due to an organic lesion or is functional is the examination of the adduction power by means of prisms. In the case of convergence paralysis of organic origin crossed diplopia will arise as soon as a prism, base out, is held before one eye. In the case of functional deficiency of convergence binocular single vision will remain, and the eye behind the rotary prism will move in accordance with the increasing strength of the prism until the limit of the adduction range is passed.

To make sure that the lack of convergence is a true paralysis of organic origin, the following conditions must be fulfilled: 1. There must be definite symptoms of an organic intracranial disease. 2. The convergence paralysis must have occurred rather suddenly. 3. The signs and symptoms tested at various times and by various methods must, in a certain measure, be constant. 4. The accommodation and the convergence reaction of the pupils must be producible without the corresponding convergence.

If internal ophthalmoplegia is accompanied by convergence paralysis, a lesion of the nuclear region and possibly also of the supranuclear pathway descending from the convergence center is certain.

DIVERGENCE PARALYSIS

Oculists are still at variance concerning divergence paralysis. Parinaud (1883) was the first to describe the signs and symptoms of divergence paralysis, and many authors have since confirmed his observations. Others, especially Berry and Alfred Graefe, have opposed the diagnosis, maintaining that the syndrome of so-called divergence paralysis should be explained in a different way.

The manifestations of a typical case of divergence paralysis include the following:

1. Homonymous diplopia, due to an abnormal convergence position, arises rather suddenly. It occurs for all objects beyond a certain distance, mostly beyond 10 to 20 inches.

2. The angle of squint being small or moderate, does not increase when the patient looks to the right or left; it will either remain the same as in the primary position of the eyes, or it will even decrease. It increases or, on the other hand, decreases when looking down or up, according to the normal anatomic conditions mentioned previously. This explains the habitual anomalous position of the head in some cases. The chin is depressed against the chest, so that by elevation of the visual lines convergence is transformed into parallelism, as has been demonstrated by photographs made of a similar case and discussed in the second paper in this series (fig. 9, p. 135, October, 1938).

3. When an object is brought nearer to the patient, the two images approach each other and are finally fused when the object is at a distance of from 10 to 15 inches. At this distance binocular single vision is maintained when looking to the right as well as to the left.

4. When the object is brought still nearer, insufficient convergence causes crossed diplopia.

5. Appropriate prisms, base out, give the patient binocular single vision, even of distant objects, in the whole field of fixation.

6. A restriction of the field of fixation is not found.

7. In repeated examinations at different times the angle of squint is found to be relatively constant.

From a theoretical point of view, the possibility of the occurrence of divergence paralysis must be conceded. On the other hand, I am convinced that in many cases a diagnosis of divergence paralysis is wrongly made. I have observed many patients with paralysis of one or both abducens nerves in whom typical symptoms were present at first, but the characteristic symptoms were gradually lost and a concomitant type of deviation developed so that it no longer increased, or, on the other hand, decreased when looking to the right and left. Sometimes this transformation may even occur within a few days. If such a paralysis is seen only in the later atypical stage, it is difficult to distinguish it from a divergence paralysis.

I have also observed patients with symptoms apparently typical of this kind of paralysis, caused by a slight convergence spasm. I remember one patient with a homonymous diplopia that had arisen four months previously. According to the report of his physician, intervals without diplopia alternated with periods during which the original diplopia was observed. The patient was extremely irritable and had been dismissed from military service on account of epileptic fits. In the first examination I found an abnormal convergence of 6 degrees when the patient's eyes were directed to a distant object. This decreased slightly when he looked to the left or to the right or up, increasing only when he looked down. When the object was brought closer, to a

distance of 15 inches, binocular single vision was obtained in the whole field of fixation, whereas crossed diplopia arose for nearer objects. Prisms of 5^A placed, base out, before each eye gave binocular single vision also for distant objects. All these symptoms coincided completely with those of typical divergence paralysis. Only repeated examinations brought discrepancies to light. When the patient opened his eyes after he had closed them for a fraction of a minute, crossed diplopia corresponding to a divergence of 2 degrees occurred, but only for a few seconds. Then the two images approached one another, fused and separated again, this time, however, as homonymous images, as the result of the gradual increase—up to 6 degrees—of convergence. Such behavior is just as difficult to reconcile with divergence paralysis as is the fact that the patient, who primarily required a prism of 5^A, base out, before each eye to obtain binocular single vision, was able to maintain it even when the strength of the prisms was diminished. He was able to maintain it even when the prism had an abducting effect, so that a divergence of 1 arc degree was produced. This, however, lasted only for a few seconds, after which his eyes went back to the usual convergent position. Thus the true nature of the case was disclosed. It was not, as had been previously diagnosed, a case of divergence paralysis but one of slight convergence spasm occasionally met with in highly neurotic persons such as our patient. Objection could be made to the diagnosis of convergence spasm since the patient displayed convergence insufficiency at reading distance, whereas in a case of spasm one would expect an increase of convergence. But it is by no means unusual to find inability to transform convergence into parallelism in combination with a weakness of the convergence innervation—a peculiarity

seen especially in neurasthenia, an important characteristic of which is the combination of increased irritability and abnormal exhaustibility.

A third anomaly might perhaps be mistaken for a divergence paralysis. If the fusion faculty is destroyed by a physical or psychic shock, an esophoria which up to that time has been unnoticed may become manifest and display symptoms similar to those of a divergence paralysis. As a rule, however, a thorough examination of the range of duction will show absence not only of divergence but also of other fusion movements.

Although it must be admitted that the differential diagnosis in many cases is extremely difficult, sometimes even impossible, I am sure that divergence innervation exists and that I have seen instances of a true divergence paralysis which not only presented the typical manifestations of the anomaly but, and this is of decisive importance, also changed rather suddenly into an equally typical case of abducens-nerve paralysis. Such a development is proof of an organic lesion, localized at first near the intact abducens nucleus but later extending to and finally injuring the nucleus itself.

TONOMETRY AND UNUSUAL CASES OF GLAUCOMA

EDWARD JACKSON, M.D.

Denver, Colorado

Our knowledge of glaucoma is still incomplete and based too much on the examination of eyes with absolute glaucoma that have been removed for pain. The tonometer, giving a mathematical statement of the hardness of the eyeball, is too much trusted as a final authority. A diagnosis should be like a court decision, based on a knowledge and right evaluation of all the facts bearing on the case. A first, provisional diagnosis may be considered as a hypothesis to help arrange the facts, so that apparently opposing facts may be compared and an estimate formed of their relative importance. But the final diagnosis should be based upon a consideration of all the facts. Often it must wait until the case has run its course; and, for some conditions, this is impossible. Not all the facts bearing upon the diagnosis are obtainable.

When a known laboratory procedure is carried over into clinical medicine, it may bias our judgment so as to disturb more than help diagnosis. When the ophthalmometer was applied to the clinical study of astigmatism, it was supposed to be an infallible guide that made cycloplegia unnecessary. Then a correction of 0.50 or 0.75 D. was found necessary for the prescribing of cylinders. Now it is known that the astigmatism of the crystalline lens changes with age, and the ophthalmometer is found to be of little practical value for the measurement of astigmatism after middle life.

Similar revisions of our estimates of values have been necessary for the Wassermann reaction, and for the various tuberculin tests. They must also be made for evidence given by the tonometer as to intraocular pressure and glaucoma. Our

understanding of glaucoma has been based on the examination of eyes destroyed by the disease. It needs to be corrected by histories of cases in which destruction of vision did not occur. Very few of these cases are found recorded in the literature. But they occur, and the reports of such cases would give us a better understanding of the real tendencies and results of glaucoma.

At the Pan-American Medical Congress, in his helpful remarks on glaucoma, Dr. Edward C. Ellett stated that we know glaucoma untreated, or inefficiently treated, goes on to blindness. The general opinion is that blindness is inevitable, unless a successful operation checks the progress of the disease. The following cases show that such may not be the result.

Case 1. C.D.L., aged 56 years, stood for many hours by her husband's death bed, exposed to severe cold, with the wind blowing on her right eye. That night she suffered terrible pain in the right eye and head; and after that she suffered from neuralgia, worse in the right eye. She was sent to me after three weeks, with the diagnosis of "grippe." The eye was hyperemic with slight pericorneal redness; the pupil ovoid, 5 mm. in diameter. The cornea was hazy, so that fundus details could not be seen; tension +2; vision, the ability to detect moving objects in the temporal field.

In the left eye the pupil was 3 mm. in size, the tension normal, the fundus normal, and vision 4/4. Operation on the right eye was urged, and eserine 1 to 2000 solution prescribed. Next day the pain was relieved, and did not return. In three weeks the cornea was clear, and the optic disc showed a slight cup, 1 diopter,

to the abrupt edge. In three months the patient had another attack, with pain, tension +2, and aching for two days. After more than a year she had continued free from any other attacks.

Case 2. Mrs. D.J. began wearing glasses at the age of 37 years, for near work only. At the age of 63 she needed for distance +3.50 D. sph., and for near +5.50 D. each, but did not wear glasses constantly. She now found the sight very poor in the left eye, 4/45 eccentric, and it felt full. There was pain around it. Pupils both were circular, 4 mm. in diameter. Tension was +1. After she had become very tired one day the eye became congested and very painful that night. Eserine 1 to 400 contracted the pupil and relieved the pain. But three days later it was extremely painful with tension of +3.

Posterior sclerectomy was done, 8 mm. back from the temporal limbus, and the anterior chamber became two thirds filled with blood. One week later pain returned, the pupil dilated to 5 mm. There was a bleb over the scleral incision. Tension was +2. These conditions continued over two weeks. Then iridectomy was done upward, and the pillars of the iris were drawn up into the subconjunctival space and caught in the angles of the scleral wound. This gave relief from pain, tension became -1, the eye comfortable. This condition continued to her death at the age of 75. The right eye continued normal, with vision of 1 +.

Priestley Smith defines glaucoma "as

an excess of pressure within the eye, plus the causes and consequences of that excess." But there are other conditions, some yet unknown, that are needed to make the dreaded disease glaucoma. We may have excess of pressure apart from glaucoma; and we may have characteristic changes of the eye, atrophy of the optic nerve, and blindness without discovering at any time an excess of intraocular pressure. So firmly fixed is the idea that increased intraocular pressure means glaucoma that serious errors are based on a tonometric reading. A few cases that have been followed up, for a number of years afterwards, show conclusively that high tension may be present for a time without any danger of glaucoma.

Case 3. Miss J.E., age 31 years, whose father had lost one eye from glaucoma, had worn glasses for aching of the eyes when at school. With the Gradle-Schiötz tonometer the intraocular pressure measured in each eye 35 mm. Hg. The fields of vision and the optic discs were normal. With correcting glasses vision was 4/3 partly in each eye. She was given pilocarpine, 1 percent solution, to use twice a day. This was discontinued within two years. At the age of 38 years her tension was 30 mm. in each eye, vision 1.2 in each, and the fundus was normal. Correcting glasses were given, and 1.25 D. sph. added for reading. She seems to have continued free from any indication of glaucoma.

FREQUENCY OF BLINKING AS A CLINICAL CRITERION OF EASE OF SEEING

MATTHEW LUCKIESH, D.Sc., AND FRANK K. MOSS*
Cleveland

It is generally assumed that visibility¹ and ease of seeing are closely related and that objects of the highest visibility are seen with the least visual effort. The latter is here defined as a subjective experience of strain which accompanies voluntary action. Thus measurements of visibility are useful in appraising the effectiveness of various controllable aids to seeing. However, if an increase in visibility is accompanied by functional changes such as an alteration in the functioning of the mechanisms of accommodation and convergence, it cannot be assumed *a priori* that an enhancement of visibility results in a decrease in the effort of seeing. For example, it is readily demonstrable that the placing of a low-power concave lens before an emmetropic eye results in a higher degree of visibility for distance vision.² However, such an addition to the refractive systems of the eyes usually cannot be worn with comfort, particularly in the performance of near-vision tasks. Thus visibility, as a diagnostic criterion in ophthalmology, is not necessarily of primary importance from the viewpoint of ease of seeing, as is qualitatively well known. In general, it is the purpose of the present paper to discuss the periodic movements of the eyelids as a criterion of ease of seeing, and as a clinical method for appraising ocular comfort.

THEORETICAL CONSIDERATIONS

A consideration of the possible physiological causes of involuntary blinking leads rather directly to the theory that this activity of the eyelids is related to

the degree of "tension" or state of "fatigue" of the subject which exists at the time. It has also been observed that the frequency of blinking is remarkably constant for the individual under constant experimental conditions.³ Obviously, the latter characteristic suggests the possibility that the frequency of blinking may serve as a practical criterion of the visual effort expended in seeing under different experimental conditions. Thus it may be possible to determine the relative degree of ocular comfort afforded by different ophthalmic corrections worn by the patient while the latter performs a critical visual task such as reading.

In briefly reviewing some of the theories related to the phenomenon of blinking, the terse statement of Duke-Elder⁴ is perhaps the most enlightening: "The causation of the movements of blinking has excited little interest. It used to be tacitly accepted that it was a reflex initiated through the fifth nerve to keep the cornea moist and to wash it clear of foreign particles. This, however, is not the case although the movements are increased by peripheral irritation." More specifically, the researches of Ponder and Kennedy⁵ suggest that the normal and periodic movements of blinking are not necessarily dependent upon impulses in the second, third, fourth, fifth, or sixth cranial nerves, and that they are also not dependent on afferent impulses arising from retina, cornea, conjunctiva, or extrinsic muscles. Thus, these investigators conclude that the eyelid movements are not of a reflex character, in the ordinary sense of the word, since there appears to be no afferent path the destruction of which causes blinking to cease.

* From the Lighting Research Laboratory, General Electric Company.

However, Adler⁵ questions the validity of this conclusion on the basis that the functions of all of these nerves were not simultaneously excluded.

Ponder and Kennedy summarize their viewpoint by stating that "the rate of blinking is closely related to the mental tension of the subject at the time, and that in all probability the movements constitute a kind of relief mechanism, whereby nervous energy, otherwise unutilized, passes into a highly facilitated path." They further conclude that "all that is necessary to occasion a change in the rate of blinking is a change in the degree of attention* of the subject."

In general, these conclusions pertaining to the physiological significance of blinking are substantiated and extended empirically by a number of researches conducted by the authors.⁶ Our results also suggest that an increase in the so-called normal rate of blinking is due, at least in part, to factors associated with fatigue. According to Blount,⁷ one of the reasons for blinking is to allow alteration to take place in the tension of the ocular muscles and thus eliminate early fatigue. The investigations of Miles⁸ indicate that the movements of blinking are associated with an upward and inward movement of the cornea of 10 to 15 degrees which is accomplished in somewhat less time than is required for the complete lid movement. If the theory of Blount is correct, it follows that the movements of the eyeball on blinking are effective in minimizing the development of muscular fatigue as well as in protecting the cornea from distortion by the tightly fitting tarsal edges of the lids and in serving other important purposes.

Thus it appears that attention, effort, and fatigue are to be considered as factors which influence the frequency of the periodic movements of blinking. In fact, Litinsky⁹ has proposed the recording of blinking as a method of studying ocular fatigue in school children while reading. This possibility heretofore has not been studied extensively. In general, previous researches on blinking have been largely devoted to the study of conditioned reflexes rather than from the present viewpoint of a criterion for appraising the effectiveness of various aids to seeing.

EMPIRICAL CONSIDERATIONS

It is axiomatic that the degree of fatigue induced by the performance of work increases as the task is prolonged. Thus the frequency of blinking should increase as a critical visual task is prolonged, if blinking is associated with effort and fatigue. This assumption has been experimentally confirmed by the authors by observing the frequency of blinking during the first and last five-minute periods of an hour of continuous reading. In general, our experimental conditions involved the reading of interesting material under three different levels of illumination by a group of 11 adult subjects possessing normal or near-normal vision. The results are summarized in table 1.

It will be noted that the frequency of blinking is higher during the last five-minute period of reading than it is during the first periods under all illuminations. The same result was invariably obtained by each of the 11 subjects. The statistical data of table 1 also indicate that the alterations in the frequency of blinking are highly significant with respect to their corresponding probable errors. Furthermore, it will be noted that the rate of blinking during the last five-minute period decreases as the task of reading is made

* Attention (behavioral concept): An adjustment of the sensory apparatus which facilitates optimal excitation by a specific stimulus or complexity of stimuli, and which inhibits the action of all others.

TABLE 1

THE NUMBER OF BLINKS OCCURRING DURING THE FIRST AND LAST FIVE-MINUTE PERIODS OF AN HOUR OF READING. THE VALUES REPRESENT THE GEOMETRIC MEANS OF THE DATA OBTAINED FROM ELEVEN SUBJECTS.

	1 Foot-candle		10 Foot-candles		100 Foot-candles	
	First	Last	First	Last	First	Last

Percent increase.....	71.5±5		31.4±3		8.3±1	

easier by higher levels of illumination.¹⁰ This is a highly significant fact, since it has been shown³ that mere photometric stimulation does not materially alter the normal frequency of blinking except for a few rapid blinks which may occur immediately after a sudden change in illumination or brightness. In fact, the so-called normal frequency of blinking is about the same in the dark as it is in the light, other conditions being constant. Thus it appears from these data that the frequency of blinking is definitely correlated with both the duration and the severity of the visual task. Similar results have been obtained under various experimental conditions which are known to be favorable or unfavorable for ease in seeing. Some of these results are briefly summarized in table 2.

The data of tables 1 and 2 show that an increase in the frequency of blinking

invariably occurs when the conditions for seeing are made more unfavorable. It will be obvious from these brief descriptions of the visual tasks that the more unfavorable conditions involve (a) the fatiguing effects of prolonged voluntary activity of the extrinsic muscles; (b) the distraction of a bright peripheral image during reading; (c) the fixation and recognition of very small details; (d) an unusual relationship between accommodation and convergence due to the red background of the reading matter; and (e) perceptual and fixational difficulties arising from closely spaced lines of print. Hence it follows that the rate of blinking is intimately related to various and complex psychophysiological factors involved in seeing, thus empirically confirming the conclusions of Ponder and Kennedy.³ Furthermore, it appears from these data that the frequency of

blinking is an extremely sensitive criterion of ease of seeing, since rather large differences in frequency are obtained between visual conditions which are commonly encountered in practice. Therefore, we have used it as a criterion for appraising ocular strain and fatigue arising from

Considering the subjects as a group, it will be noted that the minimum frequency of blinking occurred with plano lenses in addition to the usual corrections, if any. Quantitatively, the frequency of blinking was increased about 42 percent by the addition of the convex spheres and

TABLE 3

THE FREQUENCY OF THE REFLEX BLINK AS A CRITERION FOR DETERMINING THE EFFICACY OF OPHTHALMIC CORRECTIONS PRESCRIBED ACCORDING TO THE USUAL TECHNIQUES. THESE DATA DENOTE THE NUMBER OF BLINKS OCCURRING DURING FIVE-MINUTE PERIODS OF READING WHILE WEARING CORRECTIONS OF $+0.50$ DIOPTER AND -0.50 DIOPTER, RESPECTIVELY, IN ADDITION TO THE CORRECTIONS USUALLY WORN.

of indicating the proper refraction, at least with respect to the spherical component, upon the basis of comfort in seeing.

An analysis of these data with respect to individual cases indicates errors in refraction in at least 5 of the 30 cases studied. Subjects 7, 10, 15, 20, and 26 are included in this group. Among the latter it will be noted that three of these subjects do not wear glasses. It will also be noted in these six cases that the indicated errors are on both the plus and minus sides of "perfect" correction. Our interpretation of these data, for a few typical cases, follows:

Subject 2. It is apparent that the glasses worn by this subject provide maximal comfort in view of the symmetrical relationship between the frequency of blinking and the additional spherical power.

Subject 27. The sharp rise in the frequency of blinking with the addition of 0.50 diopter of minus power indicates the seriousness of overcorrecting this subject with minus lenses. Obviously, a correlation of these results with muscle-balance findings would add to the significance of the former.

Subject 25. This case is the reverse of that of Subject 27 and indicates the ocular discomfort which would result from overcorrecting with plus lenses.

Subject 6. Since an addition of 0.50 diopter of either plus or minus power produces but little change in the frequency of blinking, a slight error in correcting this subject appears to be correspondingly less serious.

The simplicity and ease with which these data may be obtained and the significance of the criterion as a measure of ocular comfort suggests the possible usefulness of this method in clinical practice. For example, this criterion might

be of value in prescribing corrections in the following situations:

- (a) In cases involving a compromise between over and under corrections as these are associated with the accommodative-convergence relationship.
- (b) In cases involving significantly different findings by subjective and objective techniques of refraction.
- (c) In cases free from refractive errors which involve an adductive insufficiency or excess.
- (d) In cases involving corrections in anisometropia.
- (e) In determining the advisability of full corrections in myopia.
- (f) In determining the benefit derived from tinted lenses.
- (g) In determining the benefit derived from iseikonic lenses.

In general, this technique seems to be applicable to those cases in which an objective and quantitative indication of ocular comfort would be of value. For example, it seems reasonable to assume that this objective criterion would be more reliable than the introspective reports of children with respect to ocular comfort; and in any case, it should be of value in prognosis. However, it is recognized that any criterion of ocular comfort applied immediately after a given change in refraction will not necessarily appraise the ultimate merit of the change since some adjustment or compensation to the new corrections may be required. On the other hand, this deficiency or inadequacy is not unique to the factor of ocular comfort as a phase of refraction.

EXPERIMENTAL TECHNIQUES

The experimental data presented in tables 1, 2, and 3 involve, with one exception, the frequency of blinking while reading. However, it is conceivable that

other activities may be suitable for clinical purposes in certain cases. For example, the data of Telford and Thompson¹³ indicate an average of 44.5 and 14.4 blinks during a five-minute period of conversation and reading, respectively, for a group of 36 subjects. These investigators suggest that the decreased blinking found during reading is not due to the mental activity involved, but possibly to several other factors; such as, the visual fixation and eye-movements involved in reading. The latter may increase or decrease the so-called normal rate of blinking. In view of these results, it is possible that the rate of blinking could be observed during conversation and while the patient was wearing the different corrections being considered from the basis of ocular comfort. It is also possible that the higher frequency of blinking during conversation would shorten the time required to obtain reliable data. An obvious objection to the latter technique is the fact that information on comfort at the near-point would not be obtained. Therefore, it seems pref-

erable to utilize unfavorable visual conditions, such as low levels of illumination, to increase the frequency of blinking for the purpose of obtaining greater precision where necessary.

The frequency of blinking may be determined either by direct visual observation or automatically through the amplification and recording of the action-currents arising during the interval of blinking. One advantage of the latter method is that longer periods of reading may be utilized. In general, we prefer the visual method, aided by a hand counter, in cases in which the periods of measurement are brief. Obviously, the duration of the experimental period depends upon the differences in visual difficulty among the situations to be appraised. In general, our experiences indicate that a period of five minutes is adequate, although in some cases it is advisable to repeat the series of measurements and use the mean values for interpretation.

FUSO-SPIROCHETAL INFECTION OF THE EYE AND ORBIT*

G. L. WALKER, M.D.

Iowa City, Iowa

Ocular inflammation resulting from infection with *Borrelia vincentii* and *Fusiformis dentium* is rare. Dunnington and Khorazo,¹ in a recent survey of the literature, collected 13 cases. In most instances other pathogenic bacteria were present in the exudate, making it difficult to evaluate the rôle played by Vincent's organisms. Gifford² has pointed out that these

bacteria probably are normal inhabitants of many mouths and that they may take advantage of conditions of lowered resistance or neglect of cleanliness, either to produce disease or to live as saprophytes on diseased tissues. Another case which tends to bear out this assumption is presented.

A 47-year-old, white woman with arthritis and secondary anemia was admitted to the University Hospital on August 28, 1937, complaining of a dis-

charging tooth socket and swelling and redness of the eyelids of the right side. The tooth socket had been draining since the extraction of a right, upper, molar tooth, three weeks previously. One week later redness and swelling of the eyelids developed and gradually increased until the day of her admission.
